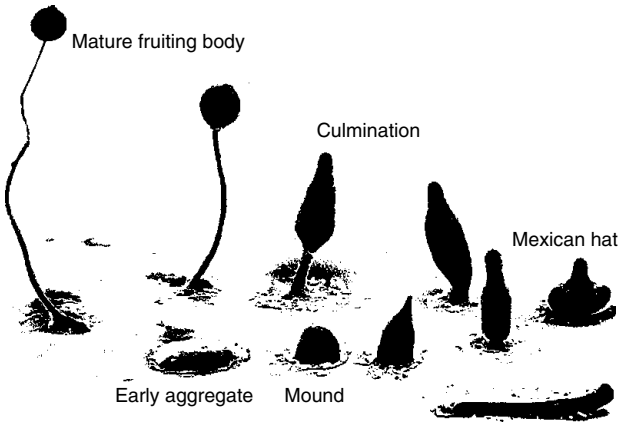
The process of mating-type switching is one of the best-understood examples of a developmentally regulated DNA rearrangement that functions in the regulatory cascades involved in cellular differentiation. A prokaryotic example involving excision of an intervening sequence (*skin*) was described in the earlier section on *Bacillus* sporulation.

3.2 Differentiation and Morphogenesis in *Dictyostelium discoideum*

Yeast differentiation is fundamentally a unicellular process – even the pseudohyphae, although multicellular, do not contain specialized cells communicating with one another and serving different functions in the whole multicellular assemblage. In this respect, the social amoeba (or cellular slime mould) *Dictyostelium discoideum* is different. In the wild, *Dictyostelium* amoebae lead a predatory lifestyle, actively hunting bacteria chemotactically (bacterially secreted folate and other pterins serving as the attractants) and feeding on them by phagocytosis. Like the prokaryotic myxobacteria, *Dictyostelium* amoebae, when starved at high density, will differentiate and aggregate chemotactically (toward secreted cAMP signals) to eventually form a multicellular fruiting body within which the cells specialize to form different tissues with different functions (Fig. 18). The choices by cells as to which differentiation pathway to take have already been made at the mound stage of development when they first differentiate into recognizably different cell types – prespores and several subclasses of prestalk cells – as revealed by differential expression of cell-type-specific genes. The different cell types have been marked by expression of reporter genes such as *lacZ* under the control of cell-type-specific promoters and their developmental fates mapped (Fig. 18). Although cells in the mounds and later stages of development



(a)

Fig. 18 Multicellular development in *Dictyostelium*. Panel A. A montage of scanning electron micrographs of stages in the *Dictyostelium* life cycle. Successive developmental stages are shown proceeding anticlockwise from the early aggregate formed by chemotactic aggregation of starving cells. The mature fruiting body is approximately 2 mm high. The original image was kindly provided by M.J. Grimson and R.L. Blanton, Biological Sciences Electron Microscopy Laboratory, Texas Tech University. Panel B. Diagrammatic representation of culmination where, for the sake of clarity, the band of pstB cells that will form the outer basal disc (see Panel C) is not shown. The *ecmA* promoter can be divided into two parts, a proximal part (the *ecmA* region) that directs expression predominantly in the cells within the tip (ie. in the pstA cells), and a distal part (the *ecmO* region) that directs expression in cells in the back of the prestalk region (the pstO cells) and in a subset (pstO:ALC cells) of the anterior-like cells (ALC). The whole *ecmA* promoter (the *ecmAO* promoter) directs expression in all these cell subtypes and has been termed the *pstAO population*. From Plate 6 of Maeda et al.(1997) *Dictyostelium discoideum – A Model Organism for Cell and Developmental Biology*. Universal Academy Press Inc., Tokyo, Japan. Image kindly provided by Prof. J.G. Williams, University of Dundee. Panel C. PstB cell behavior at culmination. The pstB cells are defined by selective staining with neutral red and because they express the *ecmB* gene at a high level relative to the *ecmA* gene. They have a complex movement pattern during slug migration. In this representation, for the sake of simplicity, separate pstA and pstO populations are not shown, but the behavior of the entire pstAO population is represented. From Plate 7 of Maeda et al. (1997). Image kindly provided by Prof. J.G. Williams, University of Dundee. (See color plate. p.xxxii)

are predestined to differentiate according to the developmental fate map shown in Fig. 18, they are not irrevocably committed to do so. In fact, right up until the final stages of differentiation with the deposition of the spore or stalk cell wall, they are able to transdifferentiate into the other cell types or even dedifferentiate and return to the vegetative state under appropriate conditions. This

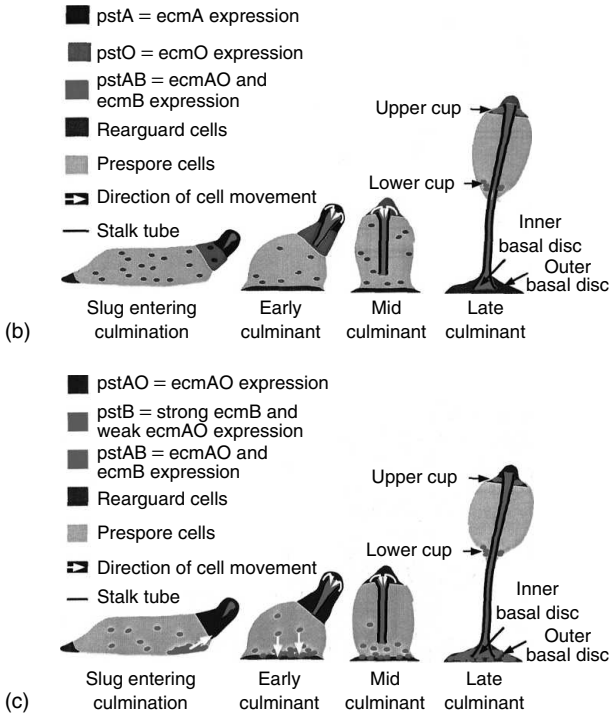


Fig. 18 (*Continued*)

developmental plasticity is important in the changeable soil environment for a fragile organism that might easily suffer mechanical injury with tissue loss during development.

Unlike the myxobacteria, *Dictyostelium* interposes between the aggregation stage and the final formation of the fruiting body, a multicellular migratory stage – the ''slug'', so called because of its superficial resemblance to garden slugs. The slug is phototactic and thermotactic – behaviors which are controlled by a specialized region in its tip and designed to take the organism to the soil surface, the most advantageous place from which to disperse the spores of the fruiting body. The slug contains several different tissues and cell types, distinguishable on the basis of subtle morphological differences and different patterns of gene expression (Fig. 18). Intercellular signals and associated intracellular signaling cascades control the initial transition from growth to development, the subsequent process of chemotactic aggregation, the formation of the slug and its motile behavior, the morphogenetic processes that transform the slug into a fruiting body as well as the spatial patterns, and proportions of its cell types. Not surprisingly, *Dictyostelium* devotes more of its ca. 12 000 genes to signal transduction than any other well-studied microorganism.

3.2.1 The Transition from Growth to Development

Like the prokaryotes *Bacillus* and *Myxococcus* and the eukaryote *Saccharomyces*, *Dictyostelium* differentiation is elicited in

response to two major signals – shortage of nutrients and signals from neighbors. At the onset of starvation at high cell density, polysomes are disassembled (and later reassembled), the expression of growth-specific genes (such as those encoding UMP- and GMP-synthetases) is repressed, and the earliest developmentally induced genes are expressed. Although the precise molecular nature of the starvation signal is not understood, at least one signal has been characterized that informs the cells of their density in a growing culture. That signal is PSF (prestarvation factor), a 65-kD protease-sensitive and heat-labile glycoprotein that is secreted into the medium. Its concentration is proportional to the cell density and reaches the threshold for eliciting development about four generations prior to the end of the exponential phase of growth. PSF induces some of the first genes to be expressed during development when added to growing cells that would otherwise not express them. These include *carA* (encoding the major cAMP receptor used during chemotactic aggregation), *pdsA* (which encodes a secreted cAMP phosphodiesterase needed during aggregation), and members of the discoidin gene family (possibly used during aggregation for cell–substratum interactions). However, this response is inhibited by the presence of bacteria, so that the PSF response effectively measures the ratio of amoebal to bacterial cell density. When exhaustion of the bacterial food supply becomes imminent, the first events in the growth to development transition are induced.

The PSF receptor has not been identified, but several intracellular signaling proteins have been identified as playing roles in the PSF signal transduction pathway (Fig. 19). YakA is a protein kinase whose absence results in cells that fail to aggregate and fail to repress growth-specific genes at the onset of starvation. YakA is a member of the family of Dyrk (Dual specificity Yak-related kinases) found in a variety of eukaryotes, including *Saccharomyces, Drosophila* and mammals, where their functions in the cell cycle and development, when known, appear to be analogous to those of YakA in *Dictyostelium*. The use of a temperature-sensitive YakA mutant allowed demonstration that it plays essential roles throughout development, downstream of G-protein-coupled receptors. PufA is a member of the pumilio/FBF family of proteins that bind to specific sequences at the 3′ ends of target RNA transcripts, preventing their translation. In this way, the *Drosophila* pumilio protein, together with the nanos protein, binds to nanos response elements (NREs) in the mRNA for the hunchback protein, inhibiting its expression. PufA in *Dictyostelium* binds to similar sequence elements found near the 3′ end of the coding sequence of the mRNA of PKA (protein kinase A, cAMP-dependent protein kinase). PufA was found by virtue of the fact that in a YakA-deficient mutant, disrupting the *pufA* gene restores starvation-induced PKA synthesis and development. PufA is expressed during growth, but disappears after a couple of hours of starvation. While present and active, it keeps PKA expression suppressed at the translational level even after transcription of the *pkaC* gene has been initiated in the earliest stages of development.

Intracellular cAMP signals, through PKA, act as master signals throughout *Dictyostelium* development and, like so many key developmental signals, are autocatalytic in nature. The genes whose transcription is induced by PKA-activated

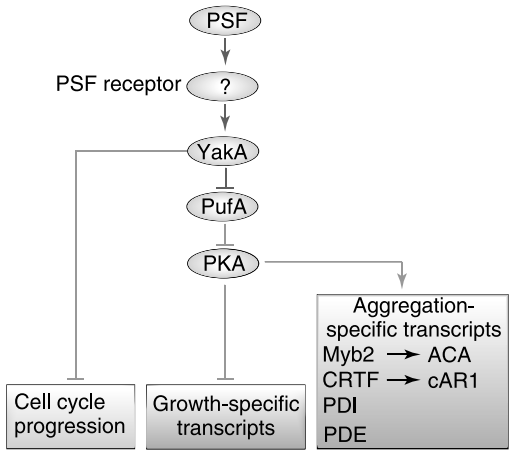

Fig. 19 The Prestarvation Factor (PSF) signaling pathway for initiating *Dictyostelium* development. PSF binds to an unknown receptor presumably belonging to the GPCR (G-protein-coupled Receptor) superfamily and elicits a signaling cascade that activates the protein kinase YakA, which, in turn, phosphorylates and inhibits the RNA-binding protein PufA. In its active, nonphosphorylated form, PufA binds to the 3′ end of cAMP-dependent protein kinase (PKA) mRNA preventing its translation. Once made and activated, PKA induces downstream genes directly or indirectly by phosphorylation of target proteins, ultimately regulating specific transcription factors such as Myb2 or CRTF (cAMP responsive transcription factor). Growth phase-specific transcripts are repressed and aggregation-specific transcripts are induced. These include those required for synthesizing and secreting cAMP such as adenylyl cyclase A (ACA) and for sensing and responding to extracellular cAMP signals, such as the cAMP receptor (cAR1). This establishes an autoactivatory feedback loop for induction of early development. YakA also phosphorylates other targets to arrest cell cycle progression at the phase shift point PS where cells exit from the cell cycle and enter differentiation. Arrowheads indicate stimulatory interactions and barred ends indicate inhibitory interactions. Blue arrows stand for interactions affecting protein expression (at the transcriptional or posttranscriptional level), and red arrows stand for interactions affecting protein activity (activation or inhibition). (See color plate. p. xxxiii)

transcription factors include those encoding the major adenylyl cyclase involved in aggregation (ACA), the cAMP receptor (cAR1), the extracellular cAMP phosphodiesterase (PDE) whose activity keeps background extracellular cAMP levels low during aggregation, and the phosphodiesterase inhibitor (PDI) that prevents premature destruction of the extracellular cAMP signal in the earliest stages of aggregation. One of the responses to extracellular cAMP is activation of ACA to produce more cAMP, which is secreted as the extracellular attractant during aggregation, but which also functions as an intracellular signal activating PKA. PKA signaling also represses growth-specific transcripts. Two of the transcription factors that participate in these signaling pathways downstream of PKA are Myb2 and CRTF (cAMP response transcription factor).

Another action of PSF signaling through YakA is to cause cell cycle arrest. Conditional YakA overexpression causes growth arrest, while growth-specific genes including *PufA* continue to be expressed in YakA-deficient mutants. As is the case with some rapidly growing embryonic cells in metazoa, the *Dictyostelium* cell cycle includes only a very short or nonexistent G1 phase. Experiments with synchronously dividing cell populations have revealed that starving cells progress about two-thirds of the way through G2 before they exit the cell cycle and differentiate. The cells that are closest to this point at the onset of starvation differentiate first, are presumably the first to start extracellular cAMP signaling, and thereby become the cells at the centers of aggregation. During subsequent differentiation in the aggregates, they preferentially differentiate into prespore cells

and ultimately into spores. The later arrivals, initially at the periphery of the aggregates, preferentially become prestalk cells, entering the tip and ultimately forming the stalk.

There are other proteins involved in the growth-to-development transition whose roles are not yet completely clear, including GdtA (a large, integral membrane protein) and AmiB, which appears to act upstream of Myb2 (as mutant phenotypes can be suppressed by ectopic expression of Myb2). Clearly, there is more to be learned about how development is initiated in *Dictyostelium*, but a solid foundation for future work has been laid.

3.2.2 Chemotactic Aggregation

PSF informs the cells of imminent depletion of the bacterial food supply and induces early gene expression in preparation for aggregation. Once the food supply has been exhausted and starvation has begun, PSF production declines and a second secreted protein called CMF (conditioned medium factor) assumes the role of a cell-density-dependent signal. CMF is an 80-kD glycoprotein whose presence is required above a threshold concentration for the onset of aggregation. Starved mutant cells lacking CMF are unable to respond to extracellular cAMP signals with the normal Ca^{2+} influx, cGMP synthesis, or cAMP synthesis, and they cannot aggregate unless CMF is supplied exogenously. However, they become responsive to cAMP within 10 s of exposure to CMF, suggesting that CMF's permissory action in aggregation is to regulate cAMP signal transduction. CMF also induces expression of a number of developmentally regulated genes including those encoding gp80 (a cell–cell adhesion molecule involved in aggregation) and SP70 (or CotB, a protein expressed in prespore cells in aggregates). The details of the CMF signaling pathways remain unknown, but there appear to be at least two CMF receptors with affinities in the nanomolar range – a G-protein-coupled receptor regulating cAMP responsiveness and a 50-kD transmembrane protein with two or three predicted transmembrane domains (CMFR1) mediating CMF-induced gene expression.

The first hours of differentiation in *Dictyostelium* render the cell competent to begin synthesizing, secreting, and responding to the chemoattractant cAMP. The cAMP signals are detected by cAMP receptors belonging to the ubiquitous eukaryotic GPCR family with their seven transmembrane domains, extracellular ligand-binding regions and intracellular signaling domains that couple to heterotrimeric G-proteins. There are 4 cAMP receptors in *Dictyostelium*, cAR1-4 encoded by the genes *carA-D*, two with high affinities (cAR1,3 – in the nM range) and two with lower affinities (cAR2,4 – in the μM range). The major receptor involved in aggregation is cAR1. Binding of extracellular cAMP to cAR1 elicits three kinds of responses:

1. Synthesis and secretion of cAMP so that the chemoattractant signal is relayed from one cell to the next.
2. Chemotactic movement toward the source of cAMP so that the cells aggregate.
3. Expression of aggregation-specific genes including those required for cAMP responses so that once it has been initiated, aggregation is an autocatalytic process.

During aggregation, the cAMP signal is pulsatile with a period of about 6 min and it spreads through the field of aggregation-competent amoebae as waves

that emanate from the aggregation center. This occurs because the cAMP signal elicits synthesis and secretion of further cAMP by neighboring cells, while at the same time extracellular phosphodiesterase degrades the cAMP left behind in the back of the passing wave. The signal transduction pathway involved in cAMP signal relay is shown in Fig. 20. Binding of cAMP to cAR1 elicits a conformational change in the receptor and dissociation of the heterotrimeric G-protein $G\alpha 2\beta\gamma$ from the receptor to release the $\alpha 2$ subunit and the $\beta\gamma$ heterodimer. The $\alpha 2$ subunit stimulates some of the downstream events involved in chemotaxis, such as cGMP synthesis, while the $\beta\gamma$ heterodimer stimulates phosphatidylinositol-3 kinases (PI3K1-3) to phosphorylate phosphatidyl inositol bisphosphate (PIP2), converting it to PIP3. PIP3 recruits the protein CRAC (cytosolic regulator of adenylyl cyclase) through its PH (pleckstrin homology) domain to the membrane from where

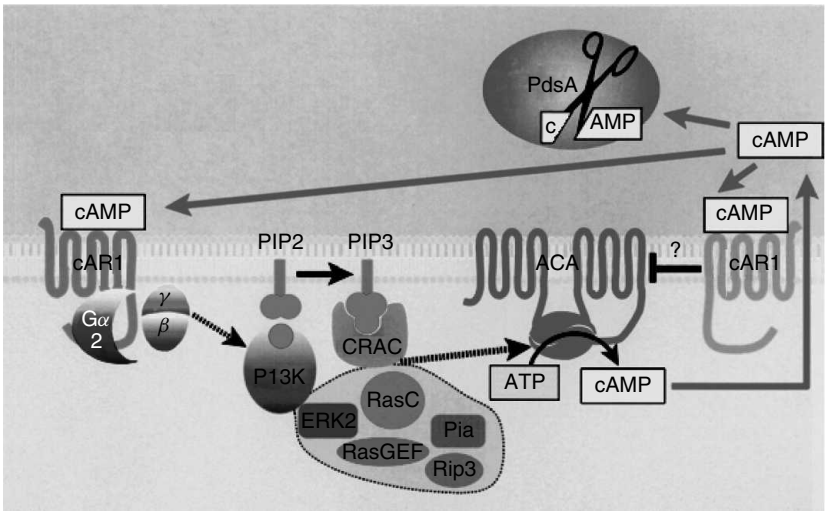

Fig. 20 The regulation of adenylyl cyclase A. Binding of cAMP to the serpentine receptor cAR1 induces dissociation of the heterotrimeric G-protein, G2, into its α and $\beta\gamma$ subunits. The $\beta\gamma$ subunits induce activation of phosphatidylinositol-3 kinase (PI3K) in a manner that is not yet understood. PI3K converts phosphatidyl inositol bisphosphate (PIP2) into phosphatidyl inositol trisphosphate (PIP3). PIP3 binds to the pleckstrin homology domain of CRAC, the cytosolic regulator of adenylyl cyclase and thereby recruits CRAC from the cytosol to the plasma membrane, where it can participate in adenylyl cyclase A (ACA) activation. A set of proteins, including the MAP kinase, ERK2, the small G-protein, RasC, the guanine nucleotide exchange factor, RasGEF, the Ras Interacting Protein (Rip3), and a novel protein, pianissimo (Pia) are also required for ACA activation. The interactions of these proteins with each other and with CRAC and ACA have not yet been clarified. cAMP produced by ACA is rapidly secreted to further activate ACA in a positive feedback loop. Binding of cAMP to cAR1 blocks ACA activation via a negative feedback loop, that is little understood. Extracellular cAMP is degraded by the phosphodiesterase PdsA, which terminates both loops and returns cells to the basal excitable state. From Fig. 2 of Saran, S., Meima, M., Alvarez-Curto, E., Weening, K.E., Rozen, D.E., Schaap, P. (2002) cAMP signaling in *Dictyostelium, J. Muscle Res. Cell Motil.* **23**, 793–802.

it activates ACA (adenylyl cyclase A). Other proteins that participate in this process include ERK2 (extracellular signal regulated kinase 2), RasC, Aimless (a guanine nucleotide exchange factor that activates Ras) and Rip3 (Ras interacting protein 3). The recruitment of CRAC to the plasma membrane occurs locally in the cell in the region of highest cAMP concentration, closest to the cAMP source. This would be the leading edge of an aggregating cell. However, the adenylyl cyclase is localized at the opposite end of the cell where synthesis and secretion of cAMP relays the attractant signal to cells further out from the aggregation center. Clearly, information must pass from the leading edge to the rear of the cell to activate ACA, but the nature of this information transfer is unknown.

Amoeboid motility involves different cytoskeletal events in different parts of the cell – pseudopod activation and extension at the leading edge, retraction in the rear. Chemotactic signals activate both of these processes in such a way as to translate a shallow extracellular attractant gradient into steep intracellular signaling and response gradients – a fast, local pseudopodium activation signal at the leading edge and a slower, global pseudopodium inhibition signal elsewhere. This spatially polarized response is not due to gradients of chemoreceptor or associated G-proteins, as fluorescently tagged forms of these are distributed uniformly or close to uniformly around the cell surface. Instead, it is the activation of PI3 kinases at the upgradient or leading edge, which exhibits the first dramatic asymmetry in chemotactic signaling events. Their action is opposed by that of PTEN, a phosphatase, which converts PIP3 (phosphatidyl inositol triphosphate) back to PIP2. After a chemotactic stimulus, the PI3 kinases phosphorylate PIP2 to form PIP3 in the membrane at the leading edge of the cell. At the same time PTEN, which is initially distributed in the cell membrane uniformly over the entire cell surface, is displaced from the front leaving it localized in the rear portions of the cell. This accentuates further the PIP3 gradient in the membranes created by the PI3 kinases. The phenotypes of null mutants show that PTEN and all three PI3 kinases in *Dictyostelium* contribute to chemotactic orientation – PI3K2 to the greatest extent, followed by PI3K1 and PI3K3. The activation of PI3 kinases involves their dynamic translocation from the cytoplasm to the membrane by an unknown recruitment mechanism that depends upon their N-terminal domains.

Once recruited to the membrane, the PI3 kinases are activated by a Ras protein through their Ras-binding domains to synthesize PIP3. This results in the recruitment of several PH domain proteins to the site including not just CRAC (see above) but also the docking protein PhDA and Akt/PKB protein kinase. PhDA acts at the leading edge to facilitate the assembly there of the necessary proteins for pseudopodial extension including F-actin. PhDA-null mutants are defective in actin assembly at the leading edge. Other proteins implicated in F-actin assembly and pseudopodium extension include the Arp2/3 complex SCAR and WASP (Wiskott-Aldrich Syndrome Protein). Amongst the target proteins for the Akt/PKB kinase is PAKa, itself a protein kinase homologous to the mammalian p21-activate kinases (PAKs). Surprisingly, in response to an attractant stimulus, PAKa translocates to the posterior of the cell where it associates with the actomyosin cytoskeleton. PAKa activity in the rear cortex of the cell inhibits myosin heavy chain kinase, causing dephosphorylation of the

myosin heavy chain by uncharacterized phosphatases. This activates myosin assembly into bipolar thick filaments, its association with actin, and its participation in actomyosin contractions. Cortical contraction of the rear of the cell is inimical to pseudopodium extension. Thus, the relocation of PAKa to the rear after its PKB-mediated phosphorylation at the leading edge provides a means whereby localized pseudopodium activation (in the front) can be coupled to and accompanied by a pseudopodium inhibition signal elsewhere (in the rear).

PTEN and PAKa are not the only signaling molecules whose site of action in chemotaxis is in the rear cortex. Attractant binding also elicits an influx of extracellular Ca^{2+} that occurs primarily in the rear cortical regions of the cell via both a G-protein-dependent and G-protein-independent pathway. A number of the actin-binding proteins that regulate its assembly into a cross-linked network of filaments are Ca^{2+}-regulated. In particular, the actin cross-linking protein, α-actinin, is Ca^{2+}-inhibited, while the actin filament severing and capping protein, severin, is Ca^{2+}-activated. The combined effect of elevated Ca^{2+} on these proteins would be a shortening of the actin filaments and a reduction in the extent of their cross-linking. This could facilitate the myosin-mediated sliding of actin filaments required for contraction of the rear cortex. However, prevention of the Ca^{2+} influx either with Ca^{2+} channel blockers or by disruption of the *iplA* (IP3-receptor-like protein) gene has no obvious effect on chemotaxis, so that the possible role for Ca^{2+} fluxes in chemotaxis remains elusive.

Another small molecule whose concentrations increase in response to an attractant stimulus (a second messenger) is cGMP. In this case, there is strong genetic evidence in the form of mutant phenotypes that cGMP plays an important role in actomyosin-mediated contractile events that inhibit pseudopodium extension in the rear cortex. The intracellular concentrations of cGMP are controlled by two guanylyl cyclases (GCA and sGC) and three phosphodiesterases (PDE3, 5, and 6), one of which (PDE6) prefers cAMP over cGMP as a substrate. The guanylyl cyclases are activated either directly or indirectly by the $\alpha 2$ subunit that has been liberated from its heterotrimeric G-protein-receptor complex by cAMP binding to the receptor. Their action is countered by the phosphodiesterases, one of which (PDE5) is itself activated by cGMP at an allosteric site separate from the catalytic site. cGMP is a small highly diffusible molecule highly suited to carrying a global pseudopodium inhibition signal to all parts of the cell upon attractant stimulation. It binds to two proteins (GbpD and GbpC) whose combined activities initiate a phosphorylation cascade terminating at the phosphorylation of the regulatory light chain (RLC) of myosin II (Fig. 21). RLC phosphorylation by MLCKA (myosin light chain kinase A) and other unidentified kinases activates both the association of myosin with the actin cytoskeleton in the rear cortex and its catalytic activity in contraction.

Chemoattractant stimulation of *Dictyostelium* amoebae has been reported to elicit a number of other molecular events whose roles in chemotaxis are unclear or controversial. These include K^+ efflux and H^+ efflux, phospholipase C-mediated release of inositol 1,4,5-triphosphate, and an associated release of Ca^{2+} from the endoplasmic reticulum into the cytoplasm. In addition, all of the described intracellular signaling processes that mediate both cAMP signal relay and chemotaxis are transient in the face of a constant extracellular

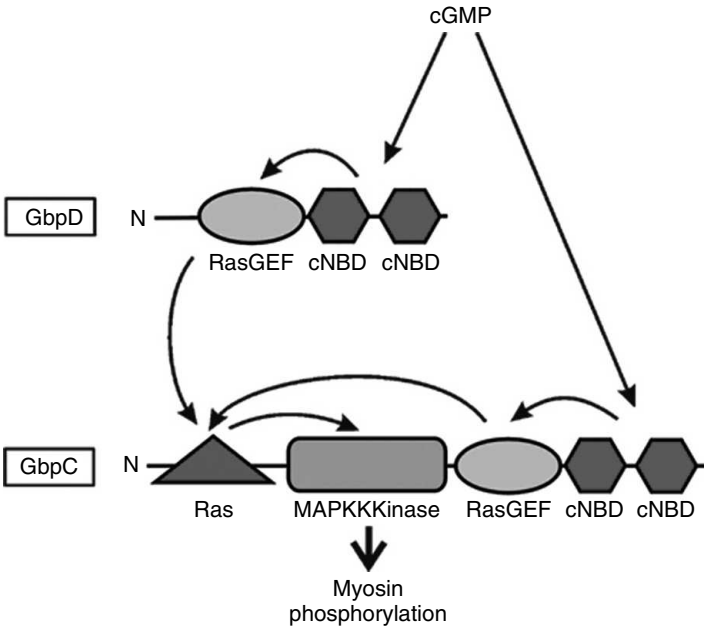

Fig. 21 Model of the function of GbpC and GbpD. The cyclic nucleotide–binding domains (cNBD) of the cGMP-binding proteins GbpC and GbpD bind cGMP, leading to the activation of the Ras guanine exchange factor domains (RasGEF), which activates the small G-protein domain (Ras) of GbpC. This results in the activation of the kinase domain of GbpC (MAPKKK), which stimulates a phosphorylation cascade eventually leading to the phosphorylation of myosin II and chemotaxis. Modified from Fig. 4 of Bosgraaf, L., van Haastert, P.J.M. (2002) A model for cGMP signal transduction in *Dictyostelium* in perspective of 25 years of cGMP research, *J. Muscle Res. Cell Motil.* **23**, 781–791.

cAMP stimulus. This is a result of adaptation processes that are poorly understood and include, but are not limited to, phosphorylation of the intracellular C-terminal domain of the cAMP receptor. The phosphorylated receptor has reduced affinity for cAMP. Adaptation not only renders the responses transient but also ensures that cells respond to relative changes in attractant concentration rather than to the absolute levels of the attractant.

The final response to pulsatile cAMP signaling during aggregation is induction of aggregation-specific gene expression. This begins with the early starvation-induced differentiation events as soon as intracellular cAMP and PKA levels are sufficient for PKA activation. However, with the arrival of each wave of extracellular cAMP, the ACA is activated and the intracellular levels of cAMP rise dramatically before most of it is secreted. The resulting pulsatile activation of PKA induces further expression of aggregation-related proteins including gp80 or contact sites A (csA), which mediates end-to-end contact of cells in aggregation streams. These contacts facilitate, but are not essential for, the natural aggregation process. Contact sites A was one of the earliest cell–cell adhesion molecules (CAMs) to be isolated from any organism and the methods used to identify

it were subsequently applied successfully to mammalian systems. During the course of aggregation, the expression of another adenylyl cyclase (ACB) is induced and, although it is not activated by extracellular cAMP signals, it contributes to basal cAMP synthesis and secretion rates and thus to the activation of PKA. Both ACA and ACB contribute to the supply of intracellular cAMP to activate PKA beyond aggregation into the later stages of development.

3.2.3 Postaggregative Development and Cell Type Choice

The result of chemotactic aggregation is that the cells crowd together into aggregation streams and then into aggregates that with time become ever more tightly packed. One consequence of this is the accumulation of a suite of extracellular protein factors that sense cell density and act to break up aggregate streams, thereby preventing aggregates from becoming too large. One of these factors is CF (counting factor), which is a high molecular weight complex (~450 kD) of several polypeptides including countin (40 kD) and CF50 (50 kD). Another of the secreted proteins affecting aggregate size is a homolog of countin called countin2 that is not part of CF. The ability of CF to promote the disintegration of aggregation streams has been attributed to the combined effects of subtle changes in cAMP signal relay, cell–cell adhesion, and actomyosin-mediated chemotactic motility.

A second consequence of cells crowding together into aggregates is that the extracellular cAMP levels experienced by the cells continue to rise during aggregation to reach micromolar concentrations in the mound and slug stages. At these concentrations, binding to the high-affinity receptors cAR1 and cAR3 is saturated so that even in the face of pulsatile cAMP signals, these receptors perceive a constant stimulus that induces expression of genes important for postaggregative development. These genes include GBF (G-box-binding factor) a transcription factor required for the expression of postaggregative genes, LagC (a cell surface signaling molecule), and RasD (a small GTPase of the Ras superfamily). GBF binds to a defined GC-rich sequence element in the promoters of these genes called the *G-box*, and is required for the transcription of both prespore-specific and prestalk-specific genes. GBF is activated by high cAMP concentrations through the cAR1 cAMP receptor in a G-protein-dependent manner. Extracellular cAMP thus acts as a cell density–sensing signal itself, coupling the progress of morphogenesis to expression of the appropriate genes.

The morphogenetic movements required for slug formation and migration as well as culmination are controlled by high concentration waves of cAMP that are relayed through the developing tissue in a manner analogous to the waves of cAMP that orchestrate the movements of aggregating cells earlier in development. These cAMP waves can be sensed by the low affinity cAMP receptors cAR2 and cAR4, which are expressed at these later stages of development.

Although high extracellular cAMP concentrations and active GBF are necessary for the expression of developmentally regulated genes during postaggregative development, they are not sufficient on their own to ensure proper morphogenesis and differentiation into the correct cell types in the correct spatiotemporal sequence. This requires additional information to inform cells of their appropriate developmental fate and position in the multicellular aggregate. This information takes two forms. The first is historical – cells that happened

to be in the mid-to-late G2-phase of the cell cycle at the time of starvation begin to differentiate and enter the aggregate first, occupying its central regions where they preferentially differentiate into prespores and ultimately spores. The later arrivals initially occupy the outer layers of the mound and preferentially locate (sort) to the tip as prestalk cells. The second type of information informing cells as to their correct developmental choices takes the form of coupled extracellular signals. These induce cells to choose either the prestalk or prespore differentiation pathways with correspondingly different locations in the aggregate and different fates in the final fruiting body (Fig. 18). They are also responsible for regulation of cell-type proportions, which remain relatively constant both in the face of major variations in slug size and after mechanical trauma to the slug, resulting in removal of parts of the tissue (such as might occur accidentally in the soil environment or be deliberately performed by an experimenter!). Slugs that have been injured in this way reorganize their tissues to form normal slugs with the correct proportions and locations of the different cell types.

The best understood of these extracellular signals is differentiation-inducing factor (DIF), a dichlorinated hexaphenone that is produced in the mound and later stages of development and induces cells to differentiate into stalk cells. In the presence of high extracellular cAMP concentrations (required both for prespore and prestalk differentiation), DIF will cause most cells in a suspension culture to enter the stalk differentiation pathway, as assayed by expression under the control of the prestalk cell-specific *ecmA* and *ecmB* promoters. DIF does this both by repressing prespore-specific gene expression and inducing prestalk-specific gene expression (although there are at least two genes expressed preferentially in prestalk cells that are not DIF-inducible, *tagB* and *carB*). The prestalk differentiation pathway leading to stalk cell formation is a form of programmed cell death that differs from, but shares some features with apoptotic and necrotic cell death pathways in mammalian cells. Interestingly enough, DIF has been found to induce cell death in mammalian cells as well, making it a potential antitumor agent.

Although the pathways involved in DIF biosynthesis in *Dictyostelium* have been elucidated, the signaling pathways involved in DIF-induced gene expression remain to be clarified – the only signaling molecule known to be involved is intracellular Ca^{2+}. DIF treatment elicits a slow prolonged elevation of intracellular free Ca^{2+} levels that temporally coincides with induction of *ecmB* expression, a marker for late prestalk differentiation. Artificially inducing a similar elevation of intracellular Ca^{2+} levels by pharmacological inhibition of ATP-driven Ca^{2+} pumps in the endoplasmic reticulum also causes *ecmB* expression. Conversely, inhibition of the DIF-induced Ca^{2+} elevation prevents *ecmB* expression. The induction of expression of an ''early'' prestalk gene, *ecmA*, by DIF precedes and is independent of the elevation of Ca^{2+} concentration. Thus, there are at least two different DIF signaling pathways – one involved in ''early'' prestalk gene expression that is independent of Ca^{2+}, and a Ca^{2+}-dependent pathway involved in ''late'' prestalk gene expression.

What is the relationship between the cell cycle–regulated and DIF-mediated choices of cell type? This was investigated by determining the DIF-sensitivity of cells starved at different stages of the cell cycle. Cells starved late in the cell cycle,

which preferentially differentiate into prespores were less sensitive to DIF than "stalk-loving" cells starved earlier in the cell cycle. Thus, the cell cycle–regulated preferences for particular cell types may be a result of differential DIF sensitivity. On the other hand, a mutant that is DIF-deficient (but not totally DIF-less) still shows relatively normal development, suggesting that cell-type choice is not completely DIF-dependent. It is possible that in normal development, cell-type preferences are initially based on the stage of the cell cycle at which cells entered starvation and that the role of DIF is to reinforce this and to generate correct proportions of the two cell types.

How would DIF allow cells to sense cell number in such a way as to produce correct cell-type proportions in the multicellular tissue of the slug? DIF is produced by prespore cells which are, however, comparatively resistant to its stalk-inductive activity. Prestalk cells are much more sensitive to DIF and also produce a DIF dechlorinase, which degrades it so that DIF concentrations in the slug are lower in the tip region. These properties can explain how DIF regulates cell-type proportions as follows. An overabundance of prespore cells would result in overproduction of DIF and underproduction of the dechlorinase so that DIF levels would rise. This would cause some cells to transdifferentiate from prespore into prestalk cells and thereby lead to a decrease in DIF levels. At some point, the decreased DIF levels would no longer be sufficient to induce further transdifferentiation, but would be sufficient to prevent the more DIF-sensitive prestalk cells from converting back into prespore cells. Conversely, if prestalk cells were overabundant, DIF levels would drop too low to prevent some of them from transdifferentiating into prespores and producing more DIF, until its levels rise sufficiently to stabilize the prestalk/prespore proportions. With DIF being responsible for regulating the proportions of prespore and prestalk cells in aggregates, their spatial separation in the slug results from the fact that prestalk (pstA) cells sort chemotactically to the tip. This differential sorting behavior of the different cell types couples the spatial arrangement of cells to their differentiation state.

The differentiation of the different cell types in *Dictyostelium* aggregates must require the activity of cell-type-specific transcription factors. Whereas GBF is a necessary transcription factor for both prestalk and prespore-specific genes, the transcription factors STATa and STATc regulate differentiation specifically in the stalk pathway. Both belong to a family of transcription factors that are activated by tyrosine phosphorylation. In mammalian cells, STAT phosphorylation is mediated by receptor tyrosine kinases (receptors with an intracellular tyrosine kinase catalytic domain) and Janus kinases (JAKs) coupled to ligand-induced receptor oligomerization. In *Dictyostelium*, no JAK homologs have been found, and the tyrosine kinases responsible for STAT phosphorylation remain unidentified. STATa induces some prestalk genes (e.g. *cudA*) and represses others (e.g. *ecmB*). The main defect in STATa deficient mutants is in precocious expression of late prestalk genes exemplified by the marker *ecmB*, so that they are expressed throughout the prestalk region. The phosphorylation of STATa is dependent on the cAR1 cAMP receptor (but independent of heterotrimeric G-proteins) and leads to its homodimerization, activation, and translocation to the nucleus. During normal development, STATa initially localizes to the nucleus in all cells in the mounds, but this is maintained

subsequently only in tip cells. Within minutes of exposing cells to exogenous DIF, STATc is phosphorylated and translocated to the nucleus. It represses *ecmA* and is responsible for the differential expression of *ecmA* in different subpopulations of prestalk cells. Like STATa, STATc can also function as an activator of gene expression, for example, in induction of *gapA* and *rtoA* expression in response to hyperosmotic stress.

The major roles of both STATa and STATc in prestalk differentiation appear to be as repressors. There must also be a positive transcriptional regulator responsible for DIF-induced prestalk gene expression. DimA is a bZIP/bRLZ family transcription factor that is required for DIF induction of prestalk genes – a DimA-null mutant produces, but is unresponsive to both endogenous and exogenous DIF.

Our understanding of the signaling molecules and pathways required for regulating cell-type choice and proportions in *Dictyostelium* is still very incomplete. Other proteins for which mutant phenotypes indicate roles in these pathways include the putative transcriptional regulators rZIP (which contains a RING-type Zn^{2+}-binding domain, a leucine zipper, and an SH3 binding motif) and Wariai (a homeobox protein preferentially expressed at the mound stage). Disruption of the genes encoding rZIP or Wariai cause, respectively, increases or decreases in the proportion of prespore cells. The upstream signaling pathways controlling cell-type proportions include MEKKα (a MAPKK kinase), whose absence causes a decrease in the proportion of prespore cells.

3.2.4 Culmination and Terminal Differentiation

Dictyostelium slugs migrate for a variable period of time determined by genotype and by environmental conditions – low humidity, high ionic strength, overhead light, low cell density prior to aggregation, and small slug size are amongst the circumstances that favor an earlier decision to cease migration and culminate. During development, *Dictyostelium* cells use as a source of energy proteins from vegetative growth and earlier developmental stages that are no longer required. Ammonia is released as a waste product of this process and is used as a morphogenetic signal. Many of the conditions that affect the decision to culminate do so by influencing the concentrations of free ammonia in and around the tip of the migrating slug – low NH_3 levels induce culmination. Overhead light, for example, causes the slugs to spend more time with their tips lifted into the air as a result of phototactic responses. This allows gaseous NH_3 to escape more rapidly from the slug with a concomitant decrease in the concentrations in the tip.

Culmination proceeds by a series of morphogenetic movements in which pstA cells enter a stalk tube funnel in the central regions of the tip and differentiate into stalk cells as they move downward in the direction of the substratum relative to other cells in the aggregate. Terminal differentiation of stalk cells involves enlargement and vacuolization of the cell, laying down of a cellulosic cell wall and, ultimately, membrane breakdown and cell death. The beginning of this process is marked by expression of *ecmB* and other late prestalk genes as the cell enters the stalk funnel. The other cells ascend the nascent stalk as it forms, and the prespore cells amongst them undergo terminal differentiation to form a droplet of spores atop the stalk in the mature fruiting body (Fig. 18). The terminal differentiation of spores involves cell dehydration and shrinkage, the

production of a peculiar cytoskeletal structure (the actin rod) responsible for the elongated, slightly curved shape of mature spores, and the laying down of the spore wall – an extracellular matrix of cellulose and proteins whose incorporation into the coat involves extrusion of the contents of specialized vacuoles found in prespore cells.

As with all of the other major stages of *Dictyostelium* development, intracellular cAMP signals activating PKA are essential for terminal differentiation. Thus, precocious maturation of both stalk and spore cells occurs in response to treatment with the active, membrane permeant cAMP analogue 8-bromo-cAMP and in mutants that overexpress the catalytic subunit of PKA (PKAC), or are deficient in the inhibitory, regulatory subunit of PKA (PKAR) or which lack RegA – a cAMP phosphodiesterase that limits the accumulation of intracellular cAMP. Conversely, maturation of both cell types is inhibited by overexpression of a mutant form of the regulatory subunit that permanently inhibits the catalytic subunit because it is no longer responsive to cAMP. These results show that a further elevation of intracellular cAMP concentrations and correspondingly higher levels of PKA activity act as the signal to permit or initiate terminal differentiation and culmination.

What causes cAMP levels to increase at the time when culmination is initiated? Current evidence indicates that extracellular ammonia signals detected by the cell surface receptor DHKC act to inhibit the initiation of culmination (Fig. 22). DHKC null mutants exhibit accelerated morphogenesis like mutants deficient in RegA or PKAR. Conversely, culmination is delayed by overexpression of a DHKC mutant form that lacks the DHKC sensor domain and may be constitutively active in signaling. This arrest in development can be overcome either by addition of 8-bromo-cAMP or by a deficiency in the RegA cAMP phosphodiesterase. The precocious culmination of the DHKC null mutant cannot be rescued by ammonia (which normally delays culmination), presumably because the mutant is unable to sense the presence of ammonia. The decision to culminate is thus mediated in normal development by a drop in extracellular ammonia levels, which relieves the DHKC-mediated activation of RegA and thereby allows intracellular cAMP levels to rise.

DHKC is one of the five histidine protein kinases found in *Dictyostelium* – homologs of the histidine kinases ubiquitously found in bacterial signaling systems. The phosphotransfer from DHKC proceeds via the phosphoshuttle protein RdeA, which has been shown by genetic suppressor analysis to lie upstream of RegA. RegA is a homolog of the bacterial response regulators with an N-terminal response regulator domain and a C-terminal cAMP phosphodiesterase catalytic domain.

For culmination to proceed successfully, morphogenesis and gene expression in differentiating spores and stalk cells must be coordinated and correctly timed. This coordination is achieved by intercellular signals that mediate communication between cells and regulate the differentiation process (Fig. 22). Two such signals have been identified. They are secreted peptides called *spore differentiation factors 1 and 2* (SDF1, molecular mass 1100 Da and SDF2, molecular mass 1300 Da), which were identified on the basis of their ability to elicit spore encapsulation in an *in vitro* assay. The encapsulation response to SDF1 takes about 75 min and

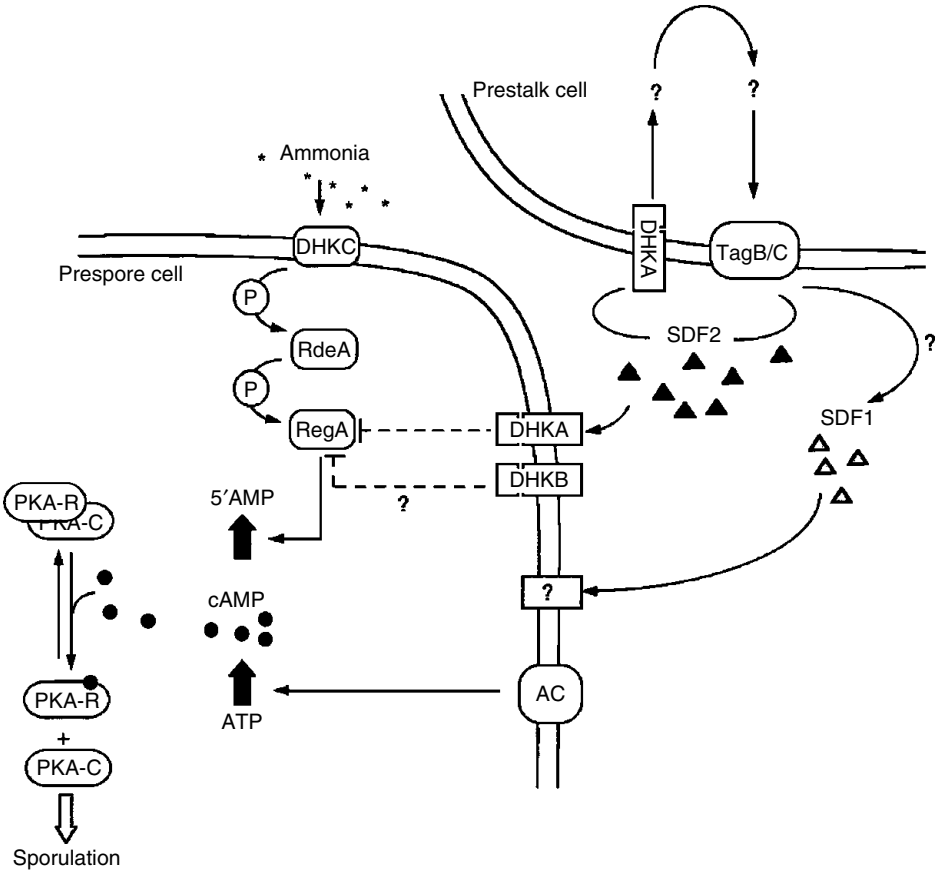

Fig. 22 Signaling pathways controlling sporulation. During culmination, protein kinase (PKA) is essential to trigger spore encapsulation. PKA activity is dependent on the level of intracellular cAMP (which controls the dissociation of the PKA-C and PKA-R subunits), which is the result of the balance between synthesis by the adenylyl cyclase (AC) and degradation by the hybrid protein phosphodiesterase/response regulator RegA. The pathway leading to the stimulation of RegA activity is proposed to be regulated by extracellular ammonia accumulation and involves a classical two component signaling phosphorelay, including the hybrid histidine kinase DHKC and the phosphodonor RdeA. Gene disruption of any of these components results in the interruption of the cascade initiated by DHKC and induces rapid sporulation. In addition to ammonia, two peptides, SDF1 and SDF2, released by the prestalk cells, have been proposed to activate intracellular pathways, the final output of which seems to be a modulation of PKA activity. SDF2 is probably processed by the protease/ABC transporter TagB/C and is probably a ligand for the histidine kinase DHKA. The downstream components of DHKA are so far unknown. DHKA shares partially redundant functions with a third histidine kinase, DHKB, a potential receptor for discadenine, an inhibitor of germination. From Fig. 5 of Aubry, L., Firtel, R. (1999) Integration of signaling networks that regulate *Dictyostelium* differentiation, *Annu. Rev. Cell Dev. Biol.* **15**, 469–517.

requires *de novo* protein synthesis, while prespore cells encapsulate in a matter of minutes in response to SDF2. SDF1 is produced at the onset of culmination when it induces the expression of culmination-specific genes, while SDF2 is made late in culmination when it elicits a wave of encapsulation that passes downward through the spore mass or sorus. SDF2 binds to the cell surface receptor DHKA, another of the *Dictyostelium* sensory histidine kinases. DHKA null mutants exhibit a specific defect in sporulation – they form fruiting bodies with long stalks and few spores. This phenotype can be rescued by 8-bromo-cAMP, by PKAC overexpression or by inactivation of either RegA or PKAR. The pathway downstream of DHKA connecting it to Reg A is unknown, but the upstream production of SDF2 has been shown genetically to involve the TagB and TagC membrane proteins expressed on prestalk cells. These proteins have a predicted protease domain, suggesting that their role in SDF2 production may be hydrolytic processing of a larger precursor polypeptide.

The final targets of signaling pathways in terminal differentiation are specific transcription factors, which are activated or inhibited as a result. In spore cell differentiation, these include Stalky and SrfA. Stalky null mutant prespore cells differentiate into stalk cells rather than spores. SrfA null mutants produce abnormal, nonviable spores. In stalk cell differentiation, one of the important transcription factors is STATa – STATa null mutants do not form stalks and fail to culminate.

3.2.5 Spore Maturation and Germination

Dictyostelium spore coats contain nine major glycoproteins (and a number of minor proteins) and the polysaccharide galuran, which are synthesized in prespore cells where they are stored in preformed complexes in specialized vesicles – prespore vesicles (PSVs). The PSV contents are the main markers for prespore cells. During encapsulation of the spores, the PSVs fuse with the plasma membrane extruding their contents, which then form the protein component of the spore coat. During subsequent spore maturation, cellulose is synthesized and extruded though the plasma membrane and the coat protein complexes bind to it via one member of the complex, SP96, which is a cellulose-binding protein. The final mature coat is 210 nm thick, and has a complex trilaminar structure with an outer protein layer, a double layer of cellulose fibrils, and an inner protein and galuran layer, with the galuran concentrated near the plasma membrane. Toward the end of spore maturation, the spore polysomes break down to single ribosomes and trehalose accumulates to high concentrations in the cytoplasm where it serves as a heat-shock protectant and as an energy source during later germination.

The spores are prevented from germinating prematurely in the sorus by extracellular accumulation of a specific germination inhibitor, discadenine (an adenine analogue), and of high concentrations of ammonium phosphate and other osmolytes. Germination is induced by removal of these (as would occur if the sorus were dispersed into the environment) in combination with a brief heat shock and in the presence of amino acids, indicating the existence of a food supply. Both discadenine and high osmolarity inhibit germination by maintaining high levels of cAMP and correspondingly high activities of PKA activity. The receptor for the discadenine signal that inhibits germination is DhkB, another of the *Dictyostelium* sensor histidine kinases that elicits high cAMP

levels by inhibiting the RegA phosphodiesterase. The osmosensor in spores is the third adenylyl cyclase of *Dictyostelium*, ACG, which is directly activated by high osmolarity to synthesize cAMP. Another signaling protein involved in germination is phospholipase C, which cleaves PIP2 to form diacyl glycerol and inositol 1,4,5-triphosphate (IP3). Diacyl glycerol in the membrane and IP3 in the cytoplasm both act as small signaling molecules (second messengers) in eukaryotes, respectively activating protein kinase C and the opening of Ca^{2+} channels in the endoplasmic reticulum. Phospholipase C–deficient mutants are unable to abort germination once it has been initiated, even in appropriate conditions that are inimical to survival of the emerging amoeba. The upstream signal for phospholipase C activation in spores and the downstream events that control abortion of germination are unknown. Spore germination is itself a developmental program that is poorly understood, but includes expression of two cellulases, which hydrolyze cellulose in the spore coat to allow emergence of the amoeba within.

4 Conclusion

The following general principles of microbial development may be gleaned from what is known about well-studied bacterial and eukaryotic systems.

1. Microbial development is usually initiated in response to nutritional stress, frequently in the form of a shortage of nitrogen combined with high cell density, which is sensed *via* secreted signaling molecules. Developmental programs presumably evolved independently in multiple lineages as a means of escaping the deadly consequences of starvation. The exception, *Caulobacter*, in which development is a constitutive part of the cell division cycle, lives in nutrient-poor aquatic environments, may be under constant nutritional stress, and so may receive little advantage by having development as an optional alternative to growth.
2. The signaling pathways that initiate development involve protein kinase cascades. Bacteria primarily use phosphorelays involving histidine protein kinases and response regulators – the so-called two-component signaling systems. Eukaryotes use tyrosine and serine/threonine protein kinases as well as histidine kinases.
3. Signaling pathways for development tend to converge upon a master regulator whose activity controls entry to major developmental stages, for example, CtrA∼P in *Caulobacter*; Spo0∼P in *B. subtilis*; PKA in *Dictyostelium*.
4. Signaling pathways for initiating development usually terminate with changes in the phosphorylation state and activity of transcriptional regulators that either induce or repress developmentally regulated genes.
5. Differentiation is coupled to the cell cycle and cells embark upon differentiation only after cell cycle arrest at a specific stage of the cell cycle. The particular cell cycle stage at which this occurs can differ in different organisms, for example, entry into gametogenesis in late G1 by yeast; onset of differentiation in middle-to-late G2 by *Dictyostelium*.
6. Development involves serially dependent, coordinate changes in gene expression whereby genes are induced in major groups under the control of common transcription factors, and

each major shift in gene expression is induced by components of the previous one, for example, sigma cascades in *Bacillus*; cAMP-elicited PKA signaling in *Dictyostelium* after the onset of starvation.

7. Transitions between the major morphogenetic stages in a developmental program involves checkpoints that couple morphogenesis to differentiation. This ensures that morphogenetic events and gene expression are coordinated, for example, septation in *Bacillus* endospore formation and the sigma factor cascade in the mother cell and the forespore; initiation of culmination by ammonia loss from the *Dictyostelium* slug when the tip is raised from the substratum for an extended time.
8. Differentiation of two or more cell types is coordinated by intercellular signals, for example, cross talk between the *Bacillus* forespore and mother cell; cAMP-, DIF- and SDF2-mediated signaling interactions between differentiating spores and stalk cells in *Dictyostelium*.

Although the details differ, these fundamental principles of development seem applicable to organisms from widely divergent groups. The reason no doubt is a combination of convergent evolution and the original presence in ancestral cells of the central mechanisms for signal transduction and gene regulation.

Acknowledgments

Keywords

Iron regulatory Protein (IRP)
Binds in response to metal occupancy to a stem loop of nucleotides called an IRE in the 5′ untranslated region of a specific mRNA to influence its translation.

Iron-responsive Element (IRE)
A specific mRNA stem-loop structure that binds an iron regulatory protein.

Metal-responsive Element (MRE)
Specific sequence of promoter region of gene that enhances transcription through a specific transcription factor (MRE-binding transcription factor) that requires metal occupancy for DNA binding.

Metal-responsive Transcription Factor (MTF)
In response to metal occupancy, translocates to the nucleus and binds to a specific MRE sequence of the DNA.

Metalloenzyme
An enzyme that requires one or more atoms of a metal for catalytic activity and/or for structure required for activity.

Trace Element Micronutrient
An essential nutrient metal required in the diet in small (μg or mg) amounts per day.

Zinc Finger
A zinc-binding domain of a protein that has an X-Cys-X_2-Cys-X_n-Cys-X_{2-5}-Cys-X (or His substituted for Cys) motif that, upon Zn(II) binding, forms a structure capable of binding DNA or RNA or interacting with another protein with a compatible zinc finger.

Trace element micronutrients is a term that refers to the metals (inorganic elements) in the diet that are essential for specific cellular processes and are required in only small amounts (mg or less) daily. In mammals, required dietary trace elements include Cu, Fe, Mn, Se, and Zn. They perform catalytic, regulatory, and/or structural roles related to gene expression. Zinc has a major role in maintaining conformations (i.e. zinc fingers) necessary for proteins to bind to specific DNA sequences (regulatory elements) or protein–protein interactions required for specific cellular functions. Zinc can also influence transcription through metal-binding proteins (metal-responsive transcription factors) that, during metal occupancy, initiate translocation to the nucleus for binding to specific DNA sequences (metal response elements) in the promoter/enhancer region of genes. Regulation of gene expression by iron can occur through metal-requiring, RNA-binding proteins. These metal-binding proteins influence translation of specific mRNAs via nucleotide sequences in the untranslated regions. Trace element micronutrients have potential applications in medicine and biotechnology either directly as signaling molecules for regulation of existing or chimeric genes or indirectly as therapeutic agents by targeting specific metal-binding sites in regulatory factors.

1
Scope of Trace Element Micronutrients in Molecular Biology

1.1
Chemical Considerations

Cellular constituents, particularly proteins, provide ligands (e.g. amine, thiolate, carboxyl, etc.) for metal binding, which follow approximately the Irving–Williams order of divalent ions: $Cu > Zn \geq Ni > Co > Fe > Mn > Mg > Ca$. Cellular transport systems regulate intracellular trace element concentrations through homeostatic control of uptake and efflux. These processes limit the influences of natural abundance and thermodynamic constraints in determining which elements participate in specific cellular functions. If ligand concentrations and metal concentrations were not controlled within cells, abnormal binding of Cu would predominate for most ligands. Only Cu, Fe, and Zn will be discussed here as these nutrients have received the bulk of attention with respect to mammalian molecular biology.

1.2
Nutritional Considerations

Micronutrients as a general term describes both essential organic molecules (vitamins) and metals (trace elements). In contrast to vitamins, metals are utilized by all living organisms to sustain cellular processes. Required trace elements include Cu, Fe, Mn, Se, and Zn. In humans, these are required in the diet in μg to mg amounts per day to maintain balance with endogenous losses. The composite cellular and extracellular need for each trace element to satisfy the needs of binding sites as balanced against turnover and endogenous losses comprises the dietary requirement for the micronutrient.

Food abundance in the developed world has minimized the incidence of deficiencies of these trace elements. Genetic variance in trace element utilization and function suggest individual requirements must be considered. This is particularly true where intakes are marginally adequate through selective diets and/or consumption of highly processed/unfortified foods. Nutritional inadequacy in the developing world is prevalent. Iron and zinc are the trace elements most likely to be in limited supply. How such nutritional deficits influence gene regulation and epigenetic effects that influence human health are active areas of investigation.

1.3
Classes of Involvement

There are three classes of involvement for trace element micronutrients (metals) in molecular biology. These are catalytic, structural, and regulatory. Metalloenzymes, where metals provide a catalytic function, comprise the first class. Another class is structural, with metals providing interaction among various binding groups of specific motifs to facilitate conformations necessary to achieve unique opportunities for specific interaction. The third class is regulatory, as exemplified by the metal binding to specific trans-acting proteins, which then provide signaling to initiate, enhance, or inhibit transcription of genes through interaction with specific DNA sequences, that is, metal-responsive elements (MRE). Metal-responsive RNA-binding proteins provide another example of regulatory involvement. These proteins, while performing a regulatory function, act through structural changes. Collectively, these classes of biological function of trace

element micronutrients are such that they provide a vital essential link between the organism and its external nutrient supply.

Eukaryotic cells employ trace elements to differing extents. Overall, zinc has the greatest spectrum of gene-related involvement through catalytic, structural, and regulatory roles in all eukaryotes. Iron and copper have catalytic roles in lower eukaryotes and a complex array of regulatory roles through metal-responsive transcription factors or metal-binding elements of RNA binding proteins. These are directed at iron and copper uptake, trafficking, and homeostasis. Most such information has been obtained using yeast (a fungus). In higher eukaryotes, copper functions in catalytic roles, while iron has catalytic and structural roles, most related to oxygen utilization. Transcriptional regulation of genes in mammalian cells is limited to zinc. The teleological explanation most likely is that zinc is redox neutral with respect to the metal atom.

1.4 Cellular Distributions

Concentrations of trace elements in various cell types vary greatly but usually are no higher than the μg/g tissue range. Frequently, such concentrations are expressed on a protein, DNA, or dry weight basis. Cells differ with respect to which organelles trace elements are most abundantly distributed. However, metal occupancy at specific binding sites, rather than concentration, determines functional effects.

Lower eukaryotes vary widely in response to the trace element content of the environment. For example, metal-resistance genes with elaborate control mechanisms have evolved to deal with elevated levels of a particular metal present in the environment through regulated transport and compartmentalization. Mammalian cells within an integrative system are not subjected to such extremes, in part through powerful homeostatic mechanisms operative at both the cell and organ level. Therefore, the tissue metal concentration in cells of animals that consume diets deficient in that essential trace element or receive an excess of that element are frequently within normal limits. Functional deficiency may occur only after depletion of a critical pool or compartment of the trace element, which then affects specific binding sites. Unfortunately, our understanding of the cell biology of trace elements lags behind our understanding of roles of these micronutrients in molecular biology.

2 Structural/Catalytic/Regulatory Roles

2.1 Metalloenzymes and Metal-binding Domains

Characterization of individual metal-binding molecules has shown that stoichiometry is usually 1 to 4 metal atoms per binding molecule. There are exceptions, for example, ferritin (4500 atoms Fe/molecule) and metallothionein (7 atoms Zn or 12 atoms Cu/molecule). In addition, abundance of metal-binding molecules ranges from a few to thousands of molecules per cell. Trace elements are essential to the enzymology of molecular biology. For example, all of the RNA nucleotide transferases (RNA polymerases) are zinc-requiring metalloenzymes. Metalloenzyme systems are not uniformly susceptible to alteration in dietary trace element restriction or supplementation.

However, many manipulations in molecular biology use metal chelation (e.g. with EDTA) as a method of controlling activity of metal-requiring enzymes.

2.2 Metalloregulatory Proteins

Metalloproteins that act as DNA-binding transcription factors, trans-acting MRE-binding proteins, mRNA-binding proteins, and proteins exhibiting metal-dependent interactions with other proteins usually bind metals through thiolate groups from cysteine (Cys) and/or nitrogen from histidine (His). Very little is known about the ligand-exchange reactions that are necessary for metals to fulfill these regulatory roles. Progress has been made regarding how dietary abundance and transport mechanisms are necessary for trace elements to meet these needs.

3 Regulation of Gene Expression by Trace Element Micronutrients

Trace elements provide signals to systems that influence rates of either gene transcription or mRNA translation. They do not act directly. Rather, through recognition that requires specific coordination chemistry, metals bind to metalloregulatory proteins (sensors or receptors) and influence signaling pathways. This ultimately augments production of a specific protein. In the classical Newtonian sense, these micronutrients (metals) act as inducers (or repressors) of the system. Since the dietary supply provides the source of the inducer (or repressor), fluctuations in intake and/or physiologic factors influencing utilization or tissue distribution of the micronutrient are determinants of how effective the trace element will be in regulating the metalloregulatory system.

3.1 Transcriptional Regulation

Examples of transcriptional regulation by trace elements are found in all eukaryotic cells, but detailed descriptions of the cellular apparatus involved have emerged more rapidly from systems in lower eukaroytes. For example, in yeast, over 100 genes that influence trace element homeostasis and cellular functions, such as defense, have been shown to be regulated by 13 different metal-responsive transcription factors. Metal transporters and chaperones comprise the largest group of these metal-regulated genes.

Metallothionein has been the most widely studied mammalian gene that is transcriptionally regulated by trace elements. Mammalian metallothionein is tissue-specific, with high expression in liver, intestine, bone marrow, pancreas, and kidney, but expression can be detected in most tissues. Depletion of the animals' dietary zinc supply has a negative effect on expression, while reduced copper intake has little effect. Similarly, elevation of dietary zinc intake level provides a positive stimulus for expression, but changes in the copper intake level have little effect. This difference between copper and zinc is an example of how mammalian systems are not analogous to metal-produced responses with unicellular organisms. In the latter, copper is an important inducer of *metallothionein*. Studies with intact animals in which trace metals are injected can show regulation by multiple inducer trace metals. These responses could be a direct action of the trace element on a sensor protein or an indirect action via transcriptional regulation signaled by metal-stimulated release

of stress-related mediators or activation of oxidant-responsive factors. Therefore, an underlying question to answer in integrative systems is whether the trace metal is a direct or an indirect mediator of gene transcription. The body of evidence with many mammalian systems, including transfected cells, demonstrates that zinc and the toxic metal cadmium (not a nutrient) induce gene expression via transcription. The exact mechanism of how zinc enters mammalian cells, traverses the intracellular space, and enters the nucleus to initiate or repress transcription has been described in limited detail. Zinc homeostasis in mammals is controlled by genes regulating influx, efflux, and compartmentalization. Some appear to be nutritionally responsive. Some transporter proteins may have metal-sensing domains and provide a signal transduction function.

At least three components are considered necessary for transcriptional regulation by a trace element (Fig. 1). First, the responsive gene must have an MRE at one or more sites in regulatory regions. All mammalian DNA motifs responsible for metal regulation thus far identified have a consensus 13 to 15 nucleotide imperfect sequence. The consensus MRE sequence for the mammalian metallothionein promoter is CTCTGCRCNCGGCCC. The core of this consensus sequence is underlined. MREs are usually found in multiple copies of either orientation within the first few hundred bases of the promoter. They are most frequently upstream from the transcription initiation site. MREs are frequently located near other regulatory elements, perhaps for synergistic or differential regulatory purposes. A search of the genome reveals that a plethora of genes have MRE sequences within regulatory regions. The proportion of these that confer transcriptional activity is not known.

The second component needed for transcriptional regulation by trace element micronutrients is a trans-acting MRE-binding metalloregulatory protein(s) called a *metal-responsive transcription factor* (MTF). Such a metal-binding/sensing protein (depicted in Fig. 1) acts as a transcription factor to initiate or enhance transcription of an MRE-regulated gene. In mammalian cells, there are only two such factors, MTF-1 and MTF-2, currently identified. Only MTF-1 has been functionally characterized. Zinc binds to MTF-1 through unique (most likely tetrahedral) coordination chemistry. MTF-1 has six (C_2H_2-type) zinc-finger domains; three bind zinc ions more strongly than the other three. The more facile sites have the regulatory role and, upon occupancy, facilitate translocation to the nucleus and DNA binding to the MRE. This may constitute the mode by which zinc from the diet activates the MTF-1/MRE system. Evidence suggests MTF-1 DNA-binding activity is influenced by phosphorylation and the state of cellular redox. Shuttling of MTF-1 between cytoplasm and the nucleus could be a point of regulation. Similarly, the *MTF-1* gene is upregulated in zinc restriction, and the *MTF-2* gene is concomitantly downregulated. Multiple MTF proteins may yield complexes that produce negative as well as positive effects on transcription of a specific MRE-regulated gene. Furthermore, tissue-specificity of metal regulation requires that genes for the MTF protein are expressed to differing extents requisite to cell function and stage of development. Data are lacking on these points. Genome screening methods, including DNA microarray analysis, have shown that numerous genes are likely regulated by MTF-1. In mice, a null mutation of *MTF-1* causes death during fetal growth. In contrast, *MT* null mice

exhibit normal growth. This difference suggests MTF-1 regulates a gene(s) other than *MT* that is critical for the developing mouse embryo. Numerous zinc transporter genes are believed to be regulated by MTF and may be among these regulated genes.

The third component for this metal-responsive unit is the trace element (metal), that is, the inducer. Intracellular concentrations of zinc, while held relatively constant, vary sufficiently with physiologic state and dietary intake to influence metal availability for binding to the MTF protein. The source (a low molecular weight chelate or a chaperone protein, possibly of lower binding affinity) and the cellular location (nuclear, cytoplasmic, or both) of metal destined for binding to MTF proteins remain to be defined (Fig. 1). It is likely that the intracellular pools for these roles may constitute only a few atoms per cell.

3.2 Translational Regulation

The initial concept of trace element control of translation was developed from the acute induction of ferritin synthesis by iron, a process that does not alter transcription of the *ferritin* gene. Iron circulates in the plasma, bound to transferrin (Tf). This protein binds to transferrin receptor (TfR) located on the cell surface, undergoes endocytosis, and contributes iron to a low molecular weight iron pool. When this cellular pool is large, ferritin synthesis is stimulated via increases in translatable ferritin mRNA. In contrast, when the cellular iron pool is low, for example, during dietary iron deficiency, translation of TfR mRNA increases (Fig. 2).

The translational regulation of TfR and ferritin mRNAs and those of other iron-regulated proteins is controlled by two cytoplasmic iron regulatory proteins (IRP-1 and IRP-2). A unique secondary structure of specific mRNAs are nucleotide loops that constitute iron-responsive elements (IRE). IREs for different mRNAs are not identical. Ferritin, TfR, the ferroportin transporter, and erythroid δ-aminolevulinate synthase are among the proteins of iron metabolism whose mRNAs have IREs. RNA-binding activity of IRP molecules is strongly regulated by dietary iron. IRP high-affinity binding to TfR mRNA causes stabilization at the A/U rich region of the 3′ end of the mRNA by inhibiting degradation and stimulating its translation. This promotes cellular iron uptake when the iron supply is low. IRP-1 may bind and thus stabilize the mRNA for the iron transporter DMT-1. This would enhance synthesis of the transporter for increased apical iron transport by enterocytes when the dietary iron supply is low. Conversely, with an increased iron supply, IRP binding to ferritin and ferroportin mRNAs is reduced, and their translation increases. This facilitates iron storage. Of interest is that slight structural differences in the 3′ end of ferroportin mRNA may cause low iron to enhance translation in the enterocytes but repress translation in liver. Iron binding is correlated with the c-aconitase activity of IRP-1. This mitochondrial TCA cycle enzyme may alter cellular citrate levels and, through iron-binding properties of citrate, influence the low molecular weight iron pool. Mitochondrial succinate dehydrogenase iron protein mRNA is also regulated by IRP-1. Iron metabolism makes further use of the IRE-IRP system for control of heme synthesis in erythroid cells via regulation of δ-aminolevulinate synthase mRNA translation.

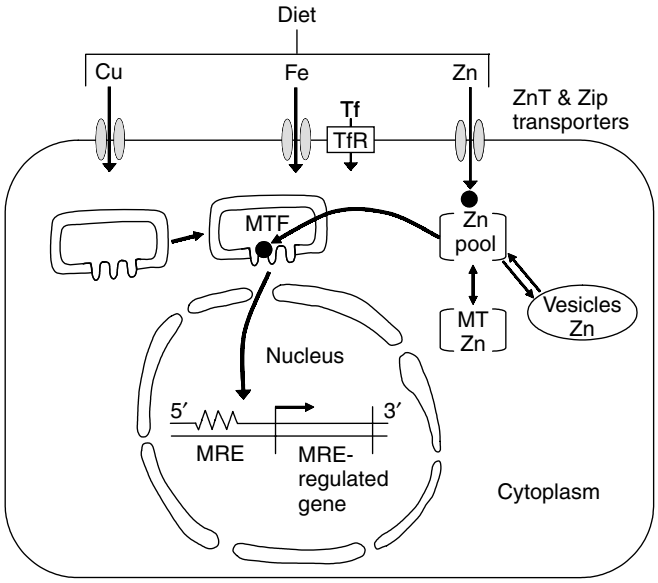

Fig. 1 Transcriptional regulation of gene expression by a trace element (metal) micronutrient. The diet provides copper, iron, and zinc for distribution to cells via the plasma. Of the three nutrients, only zinc provides a demonstrated stimulus for induction of transcription. Metallothionein gene expression by Zn provides an example of this mode of regulation. A requirement of this system is that the regulated gene(s) has a metal response element (MRE) sequence(s) in its promoter/enhancer region. The metal (●), following transport into the cell via ZnT and Zip transporters, interacts rapidly with a variety of ligands and/or is transported into vesicles, thus maintaining an extremely small pool. One of these ligands is an MRE-binding protein termed a *metal-responsive transcription factor* (MTF). Upon metal occupancy of specific zinc fingers, the MTF enters the nucleus for MRE binding. Zinc may influence the MTF translocation process and/or interaction with specific inhibitors. Phosphorylation and the cell redox state may influence these processes also. The rate of transcription is directly proportional to the dietary metal supply, the intracellular metal pool, and the extent of MTF/MRE binding. It is possible that some MRE-binding transcription factors act as negative rather than positive regulators of transcription.

4 Applications and Perspectives

The application of trace element micronutrients for control of biotechnological systems has been demonstrated. The dramatic growth of transgenic animals producing excess growth hormone through activation of chimeric metallothionein promoter-growth hormone constructs in response to zinc in the drinking water illustrated the potential of this approach two decades ago.

Chimeric constructs have been used to regulate plant genes by trace elements. The copper-responsive transcription factor

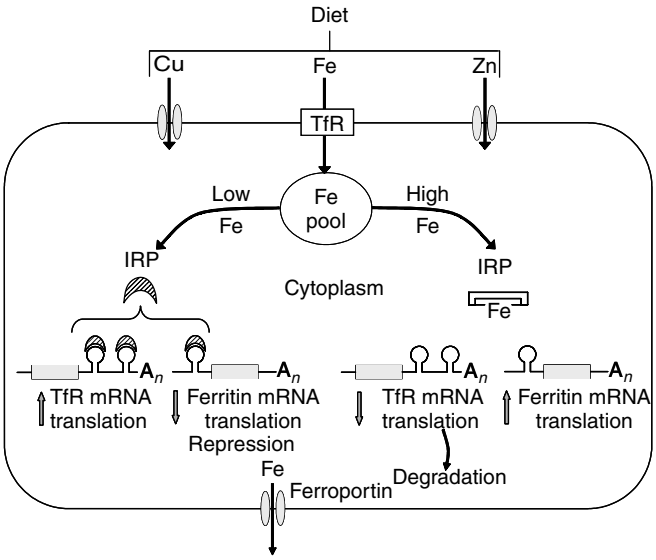

Fig. 2 Translational regulation of mRNA by a trace element (metal) micronutrient. The diet provides copper, iron, and zinc for distribution to cells via the plasma. Of the three nutrients, only iron provides a demonstrated stimulus for control of mRNA translation. Transferrin receptor mRNA (TfR mRNA) and ferritin mRNA are among the small number of mRNAs regulated by iron. The intracellular iron pool is reflective of dietary iron availability. Cellular iron is monitored by iron regulatory proteins (IRP). One IRP (IRP-1) has c-aconitase activity, which may help regulate the low molecular weight iron pool size via citrate availability. When cellular iron is low, less iron is bound to IRPs. This favors their binding to specific mRNAs via unique stem loops in the UTR of the mRNA (5′ and 3′ of the coding region for ferritin and TfR mRNAs, respectively). Binding protects TfR mRNA from degradation and increases its translation, thus transferrin receptor synthesis increases. Consequently, more iron enters the cell. Simultaneously, low iron also favors IRP binding to ferritin mRNA, which decreases translation of this mRNA. When cellular iron levels are high, iron binding to IRPs increases. This lowers the mRNA-binding affinity of IRPs, thus increasing ferritin mRNA translation and TfR mRNA degradation. As a result, ferritin synthesis increases, and TfR synthesis decreases. Erythroid δ-aminolevulinate synthase mRNA and succinate dehydrogenase mRNA translation decrease upon IRP binding with low iron in a fashion like mRNAs for H/L ferritin. Ferroportin mRNA translation in intestine is stimulated by low iron (like TfR mRNA) but, in liver, ferroportin mRNA translation is decreased. Since ferroportin is an iron export protein, this apparent difference stimulates intestinal absorption and hepatic retention.

from yeast (ACE1) was used to stimulate expression of a gene coding for a commercially important enzyme, via copper treatment of the plant. A DNA construct with the ACE1 binding site (MRE) was inserted into the promoter of the gene coding for the enzyme. Through copper treatment of the transgenic plant, production of the enzyme is increased.

A key to using trace elements for technological purposes is that those chosen must be nontoxic, for example, zinc, so as not to damage the organism but sufficiently bioavailable to promote robust expression of the transgene. The unique physiology, tissue-specific sequestration, and nutritional intake of each trace element would need to be considered in these strategies. A concern is that the metal-resistance genes of coexisting microbial systems could lead to overgrowth of endogenous microbial populations and induction of metal-inducible proteins, which may provide gratuitous changes in metabolic fates of xenobiotics. Similarly, efforts to improve micronutrient (iron and zinc) nutrition in the developing world through plants engineered to sequester more of these micronutrients could lead to overconsumption in humans and dysregulation of genes regulated by these nutrients.

The development of pharmaceuticals with actions related to metal chelation or metal donation is of major current interest. Many of these novel compounds will use trace element micronutrients as signaling systems for altering gene expression. Alternatively, a naturally occurring cellular component, for example, a zinc-finger transcription factor, could be the target of a specific trace element–containing therapeutic or sequestering agent. Similarly, engineering zinc-finger transcription factor delivered by viral vectors (gene therapy) to atypically regulate specific target genes by trace elements is possible.

Keywords

β-Barrel Cylinder
Membrane-spanning hollow cylinder formed by antiparallel amphipathic β-strands, typical in the structure of bacterial and mitochondrial outer membrane channels formed by porins.

Mitochondria
Cell organelle responsible for oxidative phosphorylation. Mitochondria are probably descendants of strictly aerobic gram-negative ancestors.

Mitochondrial (Eukaryotic Porin)
Channel-forming protein responsible for exchange of mitochondrial metabolites across the mitochondrial outer membrane.

Mitochondrial Inner Membrane
Surrounds the mitochondrial matrix space and contains the enzymes of the respiration chain and the H^+-ATPase. The mitochondrial inner membrane has many invaginations (cristae) to increase its surface and contains many carrier proteins responsible for specific substrate transport.

Mitochondrial Outer Membrane
Outer boundary membrane of mitochondria, forms with the mitochondrial inner membrane the intermembrane space that contains many different enzymes important for mitochondrial metabolism such as the mitochondrial creatine kinase.

Peripheral Kinases
Enzymes such as hexokinase and glycerokinase that bind to porin on the surface of mitochondria and utilize mitochondrial ATP.

Porin Family
Most genomes of eukaryotic cells contain more than one gene coding for mitochondrial (eukaryotic) porins. The porins form a family of highly homologous proteins that are posttranslationally imported into mitochondria.

VDAC
Voltage-dependent anion-selective channel, synonym for mitochondrial porin.

The mitochondrial outer membrane contains a channel that is responsible for the passage of hydrophilic metabolites across the membrane. The channel-forming protein known for many organisms, called *mitochondrial porin* or VDAC (voltage-dependent anion-selective channel), has a length of about 280 amino acids. The genomes of eukaryotic organisms contain several porin isoforms of not well-defined function. The primary structure of mitochondrial or eukaryotic porins is not particularly hydrophobic and secondary structure predictions suggest that a β-barrel cylinder typical for the secondary structure of bacterial porins also forms the mitochondrial channel. Kinases involved in mitochondrial metabolism such as hexokinase or glycerokinase bind to porin and play an important role in compartment formation in mitochondria. Mitochondrial porins are voltage-gated and switch into ion-permeable substates at voltages higher than 20 to 30 mV. The open channel has a small preference for anion over cations of the same aqueous mobility. The closed states are cation selective and impermeable for ATP and ADP. Mitochondrial porins seem to be involved in apoptosis and the release of cytochrome *c*. There exists emerging evidence that the cytoplasmic membrane of eukaryotic cells also contains porins of the eukaryotic porin family with a role in cellular metabolism that is not yet understood.

1 Introduction

The matrix space of mitochondria is, similar to the situation in gram-negative bacteria, surrounded by two membranes. The mitochondrial inner membrane is especially rich in proteins. Important for mitochondrial function are the enzymes of the respiration chain and oxidative phosphorylation and the many highly specific carriers for the substrates of mitochondria. In contrast to this, the mitochondrial outer membrane is far less substrate specific and acts as a molecular filter for hydrophilic solutes since it is freely permeable to a variety of small hydrophilic solutes up to a well-defined exclusion limit of about 3000 to 5000 Da. Molecules with higher molecular masses are retained. The well-defined exclusion limit indicates that the mitochondrial outer membranes contain defined passages for substrates. A considerable part of its permeability properties is caused by the presence of general diffusion pores, called *mitochondrial porins* or voltage-dependent anion-selective channels (VDACs). As early as 1976, a channel-forming component was discovered in mitochondria, but not in other membrane fractions, of *Paramecium aurelia*. Because of the voltage dependence and the anion selectivity of the channel, the name VDAC was used. It is obvious that the anion selectivity of mitochondrial porin was overestimated at the beginning because the selectivity ratio of the channel was estimated to be more than 7 for chloride over potassium ions, while more recent data suggest that it is close to 2 at neutral pH. Mitochondrial porins were isolated from a variety of mitochondria from different organisms and tissues, and there exists emerging evidence that similar proteins are also present in cytoplasmic membranes of

eukaryotic cells with yet unknown function. They form a family of slightly basic proteins with molecular masses around 30 kDa. The genes of many mitochondrial porins are known to date. The proteins are encoded in the nucleus without a leader sequence and are synthesized on cytoplasmic ribosomes. They are targeted to mitochondria as chaperone-bound species, recognized by the outer membrane general import complex (TOM) and then inserted into the outer membrane probably from the intermembrane space, similar to the situation for porins of the putative gram-negative ancestor of mitochondria.

The eukaryotic genomes may contain several genes and pseudogenes coding for porins. Mitochondria contain mostly isoform 1 (VDAC1, porin 31HL), but the role of the other one to two isoforms in eukaryotic cells was also studied. Experiments with water-soluble porin from *Neurospora crassa* and the composition of isolated mammalian porin suggest that the channel-forming unit is a complex composed of probably only one polypeptide chain and sterols. The amino acid composition exhibits a high polarity similar to bacterial porins, although the channel-forming unit is a membrane protein that contains many membrane-spanning segments. The exact structure of the pore is still a matter of debate because it has not been crystallized to date. Secondary structure predictions, electron microscopic analyzes of two-dimensional arrays and circular dichroism (CD) spectra of mitochondrial porins suggest that they contain large amounts of β-sheet structure with no indication of hydrophobic transmembrane α-helical regions, which makes it likely that bacterial and mitochondrial porins share common structural motifs. So far it is not clear if this has to do with the evolution of mitochondria or if it simply reflects that both membrane channels have water-soluble precursors.

Reconstitution experiments with planar lipid bilayers and liposomes define mitochondrial porins as pore-forming components, which have a high permeability for both ionic and neutral substrates. According to these studies, the mitochondrial outer membrane pore has a diameter of about 2 to 3 nm in the open state, which agrees well with the electron microscopic analysis of mitochondrial porin *in vitro* (i.e. in reconstituted systems) and *in vivo* (i.e. in the outer membrane The open channel appears to be wide and water filled. It is slightly anion selective for salts composed of cations and anions of the same aqueous mobility such as potassium and chloride, but may change selectivity when the anion has a smaller aqueous mobility than the cation. For membrane voltages larger than about 30 mV, the channel closes in distinct steps in several closed states. These closed states have a reduced permeability toward hydrophilic solutes and a completely different selectivity than the open state. In addition to increasing membrane potential, polyanions such as Konig's polyanion (a copolymer of molecular mass 10 kDa from methacrylate, maleate, and styrene in a 1 : 2 : 3 proportion) or dextran sulfate result in channel closure *in vivo* and *in vitro*. In particular, adenosine triphosphate (ATP) and adenosine diphosphate (ADP) are not permeable through the closed states of mitochondrial porin.

The role of the mitochondrial outer membrane in the physiology and metabolism of mitochondria was underestimated for a long time. It was described as a simple barrier that only prevented

the destruction of the mitochondrial inner membrane during osmotic swelling. More recent papers gave some insight into the function of the mitochondrial outer membrane and the role of the porin in mitochondrial metabolism. Porin is the hexokinase-binding protein and glycerokinase also binds to this protein. Cross-linking studies of the mitochondrial outer membrane of yeast revealed that the pore associates or interacts with a 14-kDa protein that was identified as glutathione transferase. Subfractionation of the mitochondrial membranes by sucrose density centrifugation allowed the isolation of contact sites between inner and outer membranes. These contact sites are especially enriched in hexokinase-binding capacity. A further interesting aspect of mitochondrial porin is its possible role in the mitochondrial permeability transition pore (PTP) and its part in cell signaling. Furthermore, there exists a strong indication that porin is involved in apoptosis because of its interaction with proapoptotic and antiapoptotic factors such as Bax and Bcl-2. Furthermore, it shows negative regulation by C-Raf kinase. This may indicate that mitochondrial porin pore plays a crucial role in the interaction of mitochondria with cellular components.

2
Reconstitution of Mitochondrial Porins (VDACs) in Model Membranes

2.1
Isolation and Purification of Mitochondrial Porins

Several different methods are well established for the successful isolation and purification of mitochondrial porins. All start from mitochondria that are obtained by differential centrifugation or density gradient centrifugation of homogenized cellular material. It has to be noted, however, that both preparations also contain other cellular material. For preparation of the mitochondrial outer membrane, the mitochondria are exposed to a swelling/shrinking procedure. Mitochondria are first exposed to 10 mM phosphate followed by addition of 0.45 M sucrose. Centrifugation at 10 000 *g* yields the mitoplasts in the pellet that also contain most of the contact sites between the inner and outer membrane. The outer membrane is in the supernatant. Porin can be isolated from the outer membrane following a standard protocol by using neutral detergents but not by ionic detergents because they destroy its channel-forming activity. A higher yield of porin may be obtained following an alternative method starting from whole mitochondria. The cell organelles are extracted with neutral detergents such as Genapol X-80, *N*,*N*-dimethyldodecylamine-*N*-oxide (LDAO) or Triton X-100. The extract is passed through a dry hydroxyapatite (HTP) column where most of the proteins bind. Porin appears just after the void volume of the column because it is deeply buried in lipid-detergent micelles and does not interact with the column material when Triton X-100 or Genapol X-80 are employed. The use of LDAO instead of Genapol or Triton obviously leads to smaller micelles that bind to HTP and allow a normal elution protocol. The use of ionic detergents such as cholate, desoxycholate, and sodium dodecylsulfate (SDS) during the isolation and purification procedure seems to destroy the structure of the channel-forming complex, and leads to its inactivity in reconstitution experiments.

2.2 Heterologous Expression of Eukaryotic Porins

It is possible to create a water-soluble form of mitochondrial porin from *N. crassa* and other organisms. Water-soluble porin is inactive in reconstitution experiments and does not form ion-permeable channels. However, when the porin is treated with Triton or Genapol in the presence of sterols, channel formation is regained with properties that cannot be distinguished from its detergent-solubilized form. It is possible that the detergents act as some kind of chaperone. Careful analyzes of the sterol requirements suggested that cholesterol leads to highest activation, whereas the addition of epicholesterol did not influence the low channel-forming ability of water-soluble porin. The possibility to refold mitochondrial porin allows an interesting insight into the structure–function relationship of porin mutants because the genes of many of the mitochondrial porins are known to date. For heterologous expression of mitochondrial porins in *Escherichia coli*, the porin-coding sequences have to be cloned in an expression vector that contains, for easy purification of the expressed protein, a DNA sequence coding for additional six histidines (His-tag) upstream of the polycloning site. This His-tag allows the purification of the overexpressed protein by Ni-NTA affinity chromatography. The expressed protein is found within inclusion bodies and needs to be solved in 1% SDS or a high concentration of urea. After chromatography across a Ni-NTA column in SDS or urea, the protein is renatured by an overnight dialysis against a 1% Genapol or Triton X-100 solution and by the addition of a cholesterol suspension in the same detergent.

2.3 Reconstitution Methods

The properties of the channels formed by mitochondrial porins (VDACs) were studied in different model membranes. Mitochondrial porins from mung bean and rat liver were investigated in lipid vesicles. The reconstitution of rat liver porin into the vesicles made them permeable for [^{14}C]sucrose, but not for [^{3}H]dextran, which suggested that a specific pathway and not a leak is introduced into the vesicles. The exclusion limit of the channel from the outer membrane of mung bean mitochondria was measured in similar experiments using radioactively labeled solutes of different molecular mass to be between 1 and 10 kDa, probably between 3 and 6 kDa. An alternative method was used for the study of porin from *N. crassa* mitochondria. Porin-containing liposomes were transferred into a hypertonic solution containing a test solute. First, the liposomes shrink and can only swell when the test solute is permeable through the channels. The results of experiments using carbohydrates and polyethylene glycols (PEG) of different molecular masses suggest that PEGs with molecular masses up to about 6.8 kDa are permeable through the mitochondrial pore. From these results, the diameter of the mitochondrial pore was calculated to be around 3 to 4 nm. It is noteworthy that this type of vesicle-swelling assay is not as precise as the swelling method used previously for bacterial porins. The reason for this is that the method used for the study of the channel diameter of bacterial porins is based on the relative rate of permeation of many different solutes through the channel, which depends on the channel diameter according to the Renkin equation.

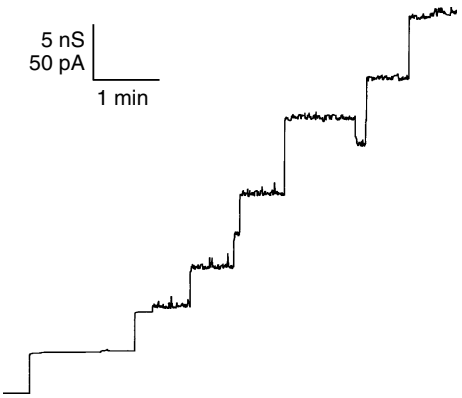

Fig. 1 Stepwise increase of the membrane current (given in pA) after the addition of *N. crassa* porin to a black lipid bilayer membrane given as a function of time. The aqueous phase contained 10 ng mL^{-1} protein and 1 M KCl. The membrane was formed from diphytanoyl phosphatidylcholine/*n*-decane. The voltage applied was 10 mV; $T = 25\,^{\circ}C$.

Many reconstitution studies with mitochondrial porins were performed using the planar lipid bilayer technique. The reconstitution is performed as follows. Purified porin is added at a low concentration (10 ng mL^{-1} to 1 µg mL^{-1}) to the aqueous phase bathing black lipid bilayer membranes formed according to the two different methods, which yield more or less similar results. After the addition of the porins to a preformed membrane, the membrane current starts increasing in a stepwise fashion after an initial lag of about 2 min (see Fig. 1 for the reconstitution of mitochondrial porin from *N. crassa*). This process indicates the insertion of ion-permeable channels into the membrane. The number of channels formed is dependent on time and the concentration of protein. In general, the membrane conductance increased for about 15 to 20 min. After that time, the membrane conductance (i.e. the current per unit voltage) increased at a much slower rate. When the rate of conductance increase was relatively slow (as compared with the initial one), it was shown for different mitochondrial porins that the membrane conductance was a linear function of the protein concentration up to porin concentrations of about 1 µg mL^{-1}. The results are consistent with the assumption that the protein samples contain preformed channels.

3 Characterization of the Pore-forming Properties of Eukaryotic Porins

3.1 Single-channel Analysis of the Mitochondrial Pore in the Open State

Mitochondrial porins from different eukaryotic cells form ion-permeable channels in lipid bilayer membranes – each step in Fig. 1 reflects the insertion of one conductive unit (i.e. of one channel into the membrane). These conductance steps are caused by the reconstitution of channels since they are not observed when only the detergents Triton X-100, Genapol X-80 or LDAO are added to the aqueous phase. Figure 1 demonstrates that most of the conductance steps are directed upwards and closing steps are only rarely observed at small transmembrane potentials of about 10 to 20 mV. The most frequent value for the single-channel conductance of mitochondrial porins in 1 M KCl (the conditions of Fig. 1) was about 4 to 5 nS (see Fig. 2 for a histogram of conductance

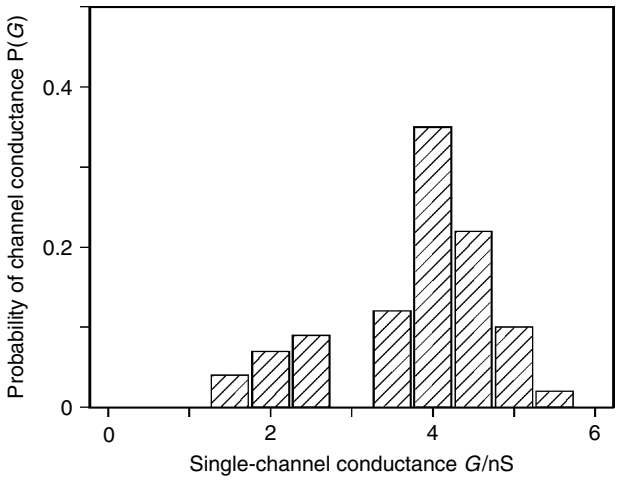

Fig. 2 Histogram of conductance fluctuations observed with membranes of diphytanoyl phosphatidylcholine/*n*-decane in the presence of *N. crassa* porin. $P(G)$ is the probability for the occurrence of a conductance step with a certain single-channel conductance (given in nS). The aqueous phase contained 1 M KCl. The voltage applied was 10 mV. The mean value of all upward directed steps was 4.2 nS for the right-side maximum and 2.5 nS for the left-side maximum (in total 187 single events); $T = 25\,^{\circ}C$.

fluctuations observed with *N. crassa* porin). Only a limited number of smaller steps were observed under these conditions (about 25% of the total number of conductance steps). It should be noted that smaller steps are also found for other mitochondrial porins, including those from yeast, rat liver, and a number of cells from other tissues including mammalian cells. They may be explained as substates of the pore with the exception of porin from *Paramecium* mitochondria, where only small pores with a single-channel conductance around 2.5 nS were observed in 1 M KCl. This result may indicate that the mitochondrial outer membrane pore does not only switch to substates but that it may also exist in two different stable conformations. The channels formed by eukaryotic porins are wide and water filled. This is the result of measurements with salts composed of different anions and cations. Even large organic anions and cations such as $Tris^+$ and $HEPES^-$, were found to be permeable through the open state of mitochondrial porins (see Table 1). The single-channel conductance of these salts is a linear function of the specific conductivity of the bulk aqueous phase at small membrane potentials.

3.2 Eukaryotic Porins are Voltage-gated

The current recording shown in Fig. 1 demonstrates that closing events represent only a minor fraction of the recordings at 10 mV transmembrane potential. At larger voltages, beginning from about 20 to 25 mV, the number of closing events increases. They are always smaller than the initial on-steps, which indicate that

Tab. 1 Average single-channel conductance of porin 31HL from human T-lymphocytes in different salt solutions.

Salt	*c [M]*	*G [nS]*
KCl	0.01	0.05
	0.03	0.15
	0.1	0.45
	0.3	1.3
	1.0	4.3
	3.0	11
LiCl	1	3.2
K-acetate	1	1.5
Tris–HCl	0.5	1.5
Tris–HEPES	0.5	0.18
K-MES	0.5	0.70

The solutions contained 5–10 ng mL^{-1} porin 31HL and less than 0.1 µg mL^{-1} of the detergent NP-40; the pH was between 6.0 and 7.0. The membranes were made of diphytanoyl phosphatidylcholine/*n*-decane; $T = 25\,^{\circ}C$; $V_m = 10$ mV. *G* was determined by recording at least 70 conductance steps and averaging over the right-hand maximum (see Fig. 2). *c* is the concentration of the salt solution.

the pores switched to ion-permeable substates at voltages higher than 20 mV. An experiment of this type is shown in Fig. 3. Transmembrane potentials of +50 and −50 mV were applied to a membrane containing first three (upper trace) and then four (lower trace) mitochondrial pores from *Paramecium*. The arrow indicates the reconstitution of the fourth channel, which closes after about 0.8 s. The membrane conductance decays in defined steps to smaller values. Similar experiments were also performed with membranes containing many mitochondrial porins, such as shown in Fig. 4. Voltages of −40 and +40 mV were applied to a diphytanoyl phosphatidylcholine/*n*-decane membrane containing about 150 mitochondrial porin channels from *Paramecium*. In this case, the closing steps cannot be resolved because of the large number of pores in the membrane. The current decays in a single exponential function (see Fig. 4). The

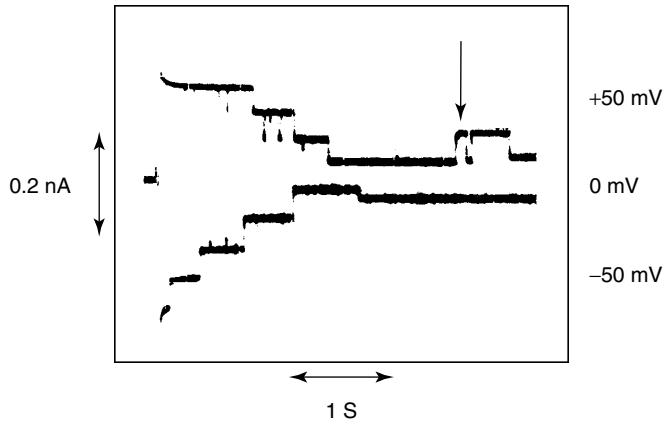

Fig. 3 Voltage-dependence of *Paramecium* porin. First a voltage of +50 mV was applied to a membrane containing three channels (upper trace). During the experiment, a fourth channel was reconstituted into the membrane (arrow), which closed after 0.8 s. Then, −50 mV was applied to the same membrane containing four channels (lower trace). The porin channels closed in defined steps. The membrane was formed from diphytanoyl phosphatidylcholine/*n*-decane. The aqueous phase contained 0.5 M Tris–HCl (pH 7.2); $T = 25\,^{\circ}C$.

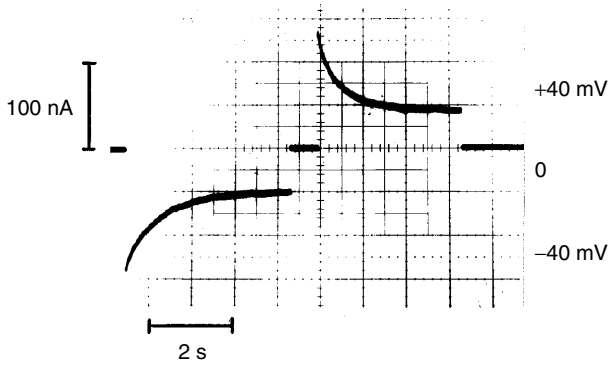

Fig. 4 Voltage dependence of *Paramecium* porin in a mutichannel experiment. About 150 porin pores were incorporated in a membrane from 1% diphytanoyl phosphatidylcholine/*n*-decane. The voltage across the membrane was switched to −40 mV (with respect to the cis-side, the side of the addition of 500 ng mL^{-1} protein) and then to +40 mV. The channels switched to substates of the open state in a single exponential curve. The aqueous phase contained 1 M KCl (pH 6); $T = 25\,^{\circ}C$.

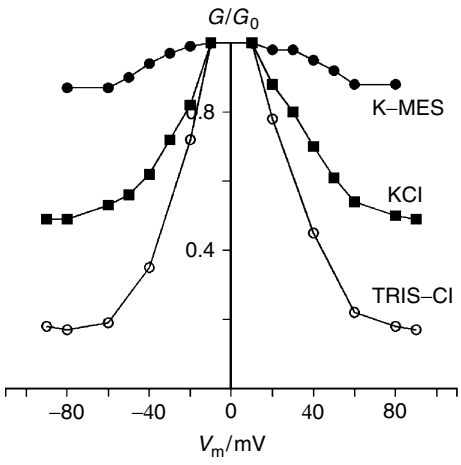

Fig. 5 Ratio of the conductance, G, at a given voltage, V_m, divided by the conductance, G_0, at 5 mV as a function of the voltage. The aqueous phase contained either 0.5 M KCl, 0.5 M K-MES or 0.5 M Tris–HCl (pH in all cases, 7.2). The cis-side contained 50 ng mL^{-1} *Paramecium* porin. The sign of the voltage is given with respect to the cis-side, the side of the addition of porin.

results of this and additional experiments at different voltages allowed the evaluation of the voltage dependence. The steady state conductance showed a bell-shaped curve as a function of the applied voltage when the conductance at a given voltage $G(V)$ divided by G_0 at zero potential is plotted as a function of membrane voltage. Figure 5 shows the results for *Paramecium* porin and three different salts (KCl, K-MES and Tris–HCl, all at pH 7.2). The results differ somewhat for different salts, although the voltage dependence is approximately the same. This has to do with the selectivity of the open channel as compared to that of the closed state (see below). The data

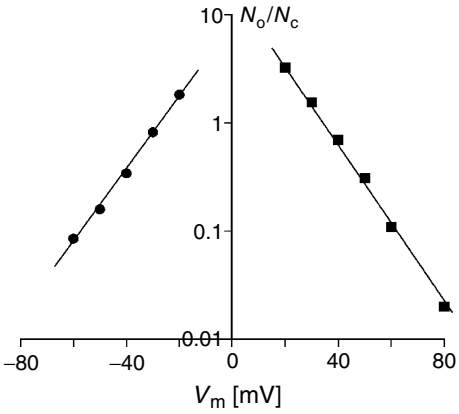

Fig. 6 Semilogarithmic plot of the ratio, N_o/N_c as a function of the transmembrane potential V_m. The data were taken from Fig. 5. The closed circles indicate the measurements with positive voltages, V_m, while the squares show measurements with negative potentials (with respect to the cis-side, the side of the addition of the protein). The slope of the straight lines is such that an e-fold change of N_o/N_c is produced by a change in V_m of 13 mV. The midpoint potential of the N_o/N_c distribution (i.e. $N_o = N_c$) is 35 mV for positive potentials (circles) and – 28 mV for negative potentials (squares). Only data for KCl are shown.

given in Fig. 5 could be analyzed as proposed previously, based on an earlier study of excitability-inducing material (EIM) by calculating the ratio of the number of open, N_o, to closed channels, N_c, from the data of the bell-shaped curves of Fig. 5:

$$N_o/N_c = (G - G_{min})/(G_0 - G) \quad (1)$$

where G is in this equation the conductance at a given membrane potential V_m, G_0 and G_{min} are the conductance at zero voltage and very high potentials, respectively. The open to closed ratio of the channels, N_o/N_c, is given by:

$$N_o/N_c = \exp[-nF(V_m - V_0)/RT] \quad (2)$$

where F (Faraday's constant), R (gas constant) and T (absolute temperature) are standard symbols, n is the number of gating charges moving through the entire transmembrane potential gradient for channel gating (i.e. a measure for the strength of the interaction between the electric field and the open channel), and V_0 is the potential at which 50% of the total number of channels are in the closed configuration (i.e. $N_o/N_c = 1$).

A semilogarithmic plot of the data given in Fig. 5 shows that they could be fitted to a straight line with a slope of 13 mV for an e-fold change of V_m (because $RT/F = 25$ mV). This result suggests that the number of charges involved in the gating process is approximately 2 in the case of *Paramecium* porin (see Fig. 6). The distribution of open and closed channels, N_o/N_c, follows a Boltzmann distribution. This means that (2) allows also the calculation of the energy difference for channel gating according to:

$$N_o/N_c = \exp[-W(V_m)/RT] \quad (3)$$

$W(V_m)$ is the voltage-dependent energy difference of one mole channels between the open and the closed state. A comparison of (2) and (3) shows that $W(V_m) = nF(V_m - V_0)$. The energy needed for channel closure, nFV_0, calculated from the data of Figs. 5 and 6 is approximately 7.7 kJ mol^{-1}, an energy that is not very high. It is considerably below the energy of one hydrogen bond, which means that channel gating is a low-energy process.

The time constant τ of the single exponential relaxation process shown in Fig. 4 decreases with increasing voltage. Interestingly, the time constants could be fitted to a similar formalism as given in (2)

for the ratio N_o/N_c, which means that a semilogarithmic plot of the time constants versus voltage yields a straight line. The slope of this line corresponded to an e-fold decrease of the time constant τ for an increase of the voltage by about 13 mV under the conditions of Fig. 4. This result suggested again that the number of gating charges involved in channel gating is about 2, which agreed satisfactorily with the number of gating charges derived from the plot of N_o/N_c (see Fig. 5). The time constant of the switching of the pores from the "closed" to the "open" state could not be followed for mitochondrial porins within the time resolution of the experimental instrumentation (about 1 ms). Figure 7 shows an experiment in which the voltage across a lipid bilayer membrane containing about 30 yeast porins was first set to 70 mV. After the exponential decay of the membrane current, the voltage was decreased to 20 mV (arrow), but no relaxation was observed (see Fig. 7). This result indicated largely different reaction rates for the closing and opening of the mitochondrial porins.

All eukaryotic porins studied to date are voltage dependent. Nevertheless, the threshold voltage for complete channel closure is somewhat different for porins from different organisms. Whereas 35 mV is sufficient to decrease the initial conductance of yeast porin to 50%, about 90 mV has to be applied to membranes containing porin from rat brain to obtain the same effect. Semilogarithmic plots of the ratio N_o/N_c showed that both V_0 and n were different in these cases. These results indicated that the number of charges involved in the gating process varies for mitochondrial porins from different organisms.

3.3 Single-channel Conductance of the Closed States

The closed state of eukaryotic porins has a reduced permeability for ions. Single-channel conductance experiments allow the evaluation of the conductance of the closed state at higher membrane potentials of 30 or 40 mV. At these voltages, the open state of the channels has only a limited lifetime because of the voltage dependence of the open state. It is possible to evaluate the single-channel conductance of the closed state by subtracting the conductance of the closing events from those of the open state. Table 2 shows the results of these type of measurements obtained for three different salts and two types of porin, from yeast and VDAC1 from a human B-lymphocyte cell line (porin 31HL). The single-channel conductance

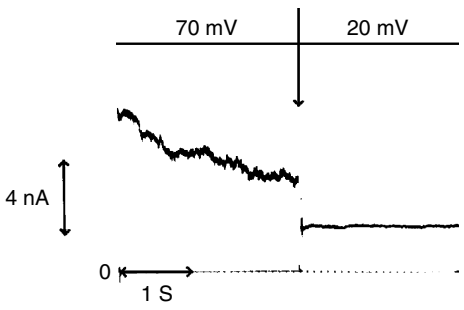

Fig. 7 Voltage dependence of the open and closed states of yeast porin. The voltage across a diphytanoyl phosphatidylcholine/*n*-decane membrane containing about 30 channels was first set to 70 mV at the cis-side of the membrane. After the relaxation of the membrane current (time constant about 1.5 s), the voltage was decreased to 20 mV (arrow). The opening of the channels was very fast (less than 50 ms) and could not be followed at the timescale of the experiment. The aqueous phase contained 1 M KCl and 20 ng mL^{-1} 1 yeast porin at the cis-side of the membrane; $T = 25\,^{\circ}C$.

Tab. 2 Average single-channel conductance of the open and closed states of yeast and human porins in different 0.5 M salt solutions.

Salt	*Open state [nS]*	*Closed state [nS]*
Yeast porin		
KCl	2.3	1.3
K-MES	0.95	0.65
Tris–HCl	1.5	0.30
Human porin (porin 31 HL)		
KCl	2.4	1.4
K-MES	0.70	0.65
Tris–HCl	1.5	0.30

The pH of the aqueous salt solutions was adjusted to 7.2. The protein concentration was between 5 and 10 ng/ml; $V_m = 30$ mV, $T = 25\,^{\circ}C$. The single-channel conductance of the closed state was calculated by subtracting the conductance of the closing events from the conductance of the initial opening of the pores.

of the closed state of the pore was considerably smaller for Tris–HCl than for K-MES, despite a similar aqueous mobility of K^+ and Cl^-. This result suggested that the closed state(s) of mitochondrial porins is cation selective.

3.4 Selectivity of the Open and Closed States of Eukaryotic Porins

The data in Table 1 suggests that ions move through the open state of mitochondrial porin in the same way they move in the bulk aqueous phase. Interestingly, the pores also exhibit certain specificity for charged solutes because the single-channel conductance in potassium acetate is somewhat smaller than that in LiCl despite the same aqueous mobility of lithium ions as compared to acetate (see Table 1). This means that the mitochondrial porin is selective although it is a wide and water-filled channel in the open state. Experiments with lipid bilayer membranes under zero-current conditions and an externally applied concentration gradient, c''/c', across the membrane allow the evaluation of the ionic selectivity. From the membrane potential, V_m, caused by the preferential movement of one sort of ions through the channel, the ratio P_{cation}/P_{anion} of the permeabilities for cations and anions can be calculated using the Goldman–Hodgkin–Katz equation.

Table 3 shows the zero-current membrane potentials and the permeability ratios for different mitochondrial and eukaryotic porins [porin 31HL (human), rat liver, yeast, and *Paramecium*] in potassium chloride, potassium acetate, and lithium chloride. It is obvious from the data of Table 3 that the asymmetry potential and

Tab. 3 Zero-current membrane potentials, V_m, of membranes from diphytanoyl phosphatidylcholine/*n*-decane in the presence of rat liver, yeast, and *Paramecium* mitochondrial porins measured for a 10-fold gradient of different salts[a].

Salt	V_m *[mV]*	P_{anion}/P_{cation}
Rat liver		
KCl (pH 6)	−11	1.7
LiCl (pH 6)	−24	3.4
K acetate(pH 7)	+14	0.50
Yeast		
KCl (pH 6)	−7	1.4
LiCl (pH 6)	−20	2.6
K acetate (pH 7)	+14	0.5
Paramecium		
KCl (pH 6)	−11	1.7
LiCl (pH 6)	−24	3.4
K acetate (pH 7)	+14	0.50

[a] V_m is defined as the potential of the dilute side (10 mM) relative to that of the concentrated side (100 mM); the temperature was 25 °C. P_{anion}/P_{cation} was calculated from the Goldman–Hodgkin–Katz equation.

the ion selectivity of mitochondrial porins are dependent on the combination of different anions and cations. The different porin channels are slightly anion selective (ratio $P_{cation}/P_{anion} = 2:1$) for potassium and chloride, which have approximately the same aqueous mobility. For the combination of the less mobile lithium ion (because of its larger hydration shell) with chloride, the anion selectivity increases. Since the ions move within the channel in a similar way as in bulk aqueous phase, the channel becomes cation selective for potassium acetate because of the smaller mobility of acetate as compared with potassium ions. This result represents another support for the assumption of the mitochondrial pore as a wide water-filled channel in the ''open'' state.

The open state of all mitochondrial porins characterized so far is slightly anion selective for salts composed of equally mobile cations and anions such as KCl (see above). The mitochondrial porins switch to closed states when the transmembrane voltage exceeds 20 to 30 mV. These states definitely have reduced ion permeability as the bell-shaped curves of Fig. 5 clearly indicate. The ion selectivity of the closed states cannot be measured using zero-current membrane potential measurements with pores in the closed state. However, the results of Fig. 5 and Table 2 suggest that the closed state is cation selective since for the combination K-MES (a mobile cation combined with a less mobile anion) the conductance in the open and in the closed states differs only little. The difference between open state and closed state is more substantial for Tris–HCl (a mobile anion combined with a less mobile cation). This result suggests indeed that the channel is cation selective in the closed state.

4 Inhibition of the Mitochondrial Pore

Konig and coworkers showed that an amphiphilic, synthetic polyanion (a copolymer of 10 kDa molecular mass of methacrylate, maleate, and styrene in a 1 : 2 : 3 proportion) inhibits different carriers in the mitochondrial inner membrane and the ATPase. It is possible that these effects have nothing to do with a direct interaction between the polyanion and inner membrane carriers. Moreover, it seems that the polyanion binds to mitochondrial porin and shifts its voltage dependence in a defined way, thus closing the channel when the membrane voltage has a negative sign at the cis-side, the side of the addition of the polyanion. For a positive potential at the cis-side, the channel is always in its open configuration even for voltages up to 120 mV and higher. The effect of the polyanion on mitochondrial porin from rat liver is demonstrated in Fig. 8. First the voltage dependence of reconstituted rat liver porin was studied and showed the typical bell-shaped curve. The polyanion was added at a concentration of 100 ng mL^{-1} polyanion to one side of the membrane (the cis-side). When the voltage had a negative sign on the cis-side, the membrane current started to decrease at smaller voltages than without the polyanion. A membrane potential of −10 mV was already sufficient to close the channels. Higher voltages (−40 mV; see Fig. 8) resulted in a more rapid closure of rat liver porin (relaxation time constant smaller than 100 ms), whereas +40 mV had no effect on porin-induced membrane conductance. Even voltages with magnitudes up to +120 mV did not result in any current decrease, which means that the polyanion stabilized the pore in the open state if the sign of the transmembrane

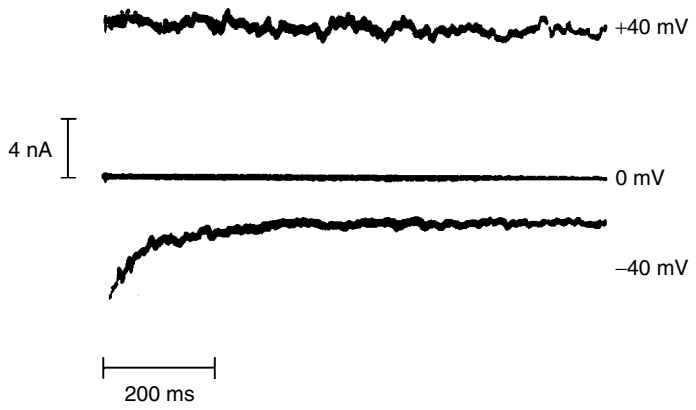

Fig. 8 Asymmetric current response of rat liver porin after application of membrane potentials of different polarity. The membrane was made of asolectin/*n*-decane. The concentration of the porin was 100 ng mL^{-1} in the 1 M KCl solution. The cis-side contained in addition 1μg mL^{-1} polyanion. A membrane potential of +40 mV (upper trace) and −40 mV (lower trace) was applied to the membrane (referred to as the *cis-side*) 40 min after the addition of the porin and 10 min after that of the polyanion. Note that the membrane current only decreased if the cis-side was negative; $T = 25\,^{\circ}C$.

potential was positive on the cis-side. The addition of the polyanion to both sides resulted in a bell-shaped curve because the channels closed at positive and negative potentials. However, the parameters of channel closure were completely different to those without polyanion, that is, n was much larger (about 4–5) and V_0 was smaller than 10 mV. The experimental data suggest that there does not exist a "sideness" for the interaction of the polyanion with porin, which means that the polyanion can interact with the gate(s) from both sides of the channel. Furthermore, the asymmetric effect of the polyanion on rat liver porin was stable during the whole lifetime of the membranes (up to several hours), indicating that the polyanion could not penetrate the channel.

The interaction of the polyanion with mitochondrial porins from different sources also allows us to measure the conductance of the closed state when the polyanion was added at a concentration of 100 ng mL^{-1} to the side of the membrane with negative polarity (the cis-side). The single-channel conductance was about half that of the open state measured at low voltage, which means that the closed channels are still permeable for ions, which makes a direct polyanion-induced block of the channel rather unlikely. Table 4 shows the effect of polyanion on the single-channel conductance obtained with salts other than KCl. The reduction of the single-channel conductance caused by the polyanion is especially large when a mobile anion (e.g. Cl^-) is combined with a less mobile cation (e.g. $Tris^+$). In this case, the single-channel conductance was reduced to less than 10% of the open state value. The effect of the polyanion on combinations of mobile cations with less mobile anions (e.g. on K-MES) was very small. These results are consistent with the assumption that the slightly anion-selective channel in the

Tab. 4 Average single-channel conductance of the open and the polyanion-induced closed state of rat liver mitochondrial porin in different 0.5 M salt solutions. (The pH of the aqueous salt solutions was adjusted to 7.2. The membrane voltage was 10 mV at the cis-side; $T = 25\,^{\circ}C$. The aqueous phase contained in the measurements of the closed state 0.1 μg mL^{-1} polyanion added to the cis-side).

Salt	*Open state [nS]*	*Closed state [nS]*
KCl	2.2	1.2
LiCl	1.8	0.40
K acetate	1.1	0.85
K-MES	0.88	0.74
Tris–HCl	1.5	0.25

open state becomes highly cation selective in the closed state (see also Fig. 5). This was also the result of selectivity measurements in the presence of polyanion. The ratio P_{cation}/P_{anion} for rat liver porin in selectivity measurements without polyanion is approximately 0.6 for KCl. For a polyanion concentration of 15 μg mL^{-1} on both sides of the membrane, P_{cation}/P_{anion} increases to about 10, which suggests that chloride has a very small permeability through the polyanion-mediated closed state of rat liver porin.

Channel blockage by the polyanion can be compared to the situation in whole mitochondria in which polyanions added to the outside (presumably the negative side of the outer membrane) are able to close the channel and inhibit the passage of anionic metabolites across the mitochondrial outer membrane, including ADP and ATP, thus blocking the mitochondrial metabolism. Other polyanions such as dextran sulfate have a similar effect on the voltage dependence of mitochondrial porin, but these compounds need a considerably larger concentration for channel closure than the polyanion. In addition to the different polyanions, the action of a protein component from mitochondria was studied in mitochondria and in reconstituted systems. This ''modulator'' exhibits a similar action on the porin channel as the polyanion, which means that it disturbs nucleotide exchange across the outer membrane and shifts the voltage dependence of the channel in a dose-dependent way. Although its action is known, it has not been possible to identify the modulator. It is presumably a polypeptide since it is susceptible to pronase, that is, its action on porin is destroyed by pronase treatment.

5 Structure of the Channel Formed by Eukaryotic Porins

5.1 Primary Structure of Eukaryotic Porins

The primary structure of eukaryotic porins from many organisms, including humans, mouse, fruit fly, plants, yeast, fungi, and *Dictyostelium*, is known to date. With the exception of porin 31HL (HVDAC1 from humans), all were derived from their cDNA sequences. Porin 31HL is known from its amino acid sequence. Despite many variations of single amino acids, all sequences are related to one another and have an approximate length of about 280 amino acids. Figure 9 shows a comparison of the amino acid sequences of human (HVDAC1, porin 31HL), *Drosophila melanogaster*, potato, *Saccharomyces cerevisiae* and *N. crassa* mitochondrial porins. Despite the clear homology between the different sequences, only 15 (out of about 280) amino acid residues are strictly

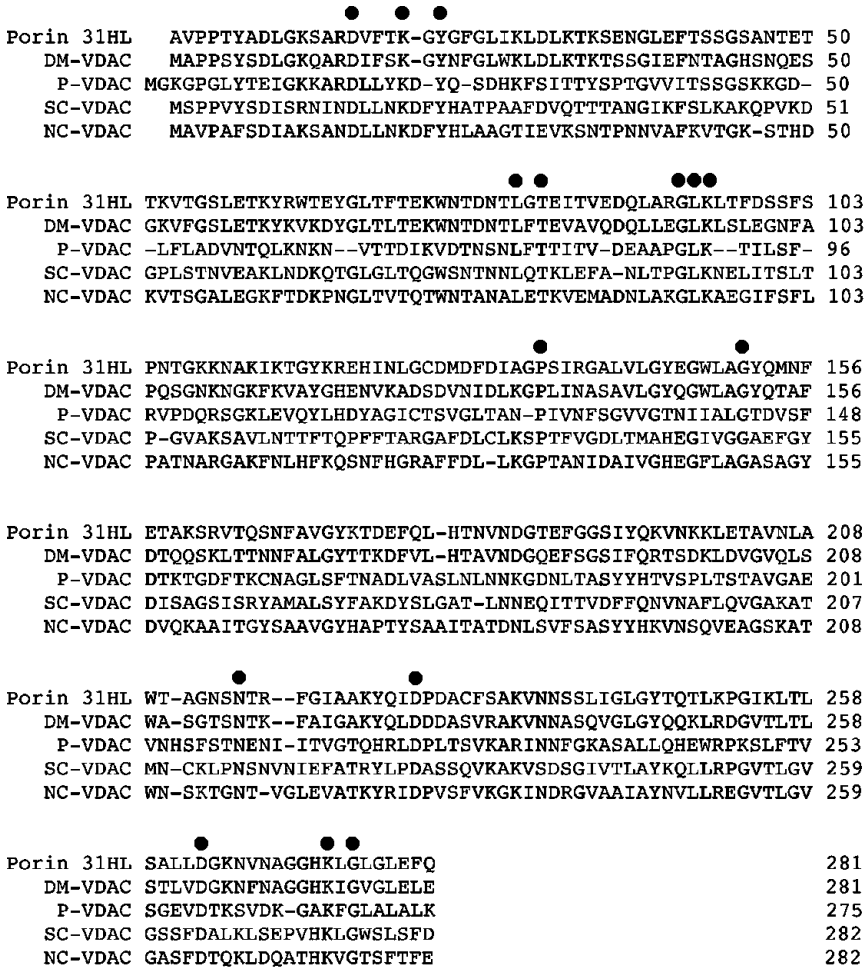

Fig. 9 Comparison of the amino acid sequences of human (HVDAC1, porin 31HL), *D. melanogaster*, potato, *S. cerevisiae* and *N. crassa* mitochondrial porins using BLAST. Three or more identical amino acids are shaded. Points indicate identical amino acids in all five sequences.

conserved in all five porins (marked by points in Fig. 9). The most remarkable identity in all five porins is the GLK triplet near amino acid 90, which may play an essential, but unknown, role in eukaryotic porin function. However, it is not the place of ATP binding. Otherwise, the identities between the five porins are rather small in large stretches of the aligned porin sequences. These results suggest that the possible β-barrel structure of mitochondrial porins (see below) tolerates extensive amino acid variations without substantial alterations in the secondary structure and of the function of a voltage-dependent membrane channel, which was found for all the mitochondrial porins. Similarly, all porins form wide water-filled

channels with an average single-channel conductance of about 4 nS in 1 M KCl, that are slightly cation selective in the open state and highly cation selective in the voltage-dependent closed state.

No identity exists between primary sequences of mitochondrial porins and those of bacterial porins, especially of phototrophic bacteria, which are related to the ancestor of mitochondria. On the other hand, the structure and function of bacterial porins as channels are clearly similar to those of the mitochondrial porins, since they both contain predominantly antiparallel β-barrel stave structures, which form hollow cylinders in the outer membrane and they both have similar molecular masses. Hydropathicity plots indicate that the primary sequence of mitochondrial porins is predominantly hydrophilic (46–50% polar residues). This clearly distinguishes them from the ion channels in nerve and muscle tissue with their typical α-helical structure, although the p-elements of potassium and similar ion channels contain an approximately 20-amino acid stretch that lines the channel and is organized similar to a β-sheet structure. Eukaryotic porins contain only about a 19-amino acid long stretch at the N-terminal end that may form an α-helical region. The function of the amphipathic α-helical structure is still a matter of debate, and it is suggested that it has to do with channel gating; protein targeting or it is even a part of the channel itself.

5.2 Secondary Structure of Mitochondrial Porins

The secondary structure of most mitochondrial porins was analyzed using computer-based prediction programs. The simplest possibility of identifying amphipathic β-strands is the method proposed by Vogel and Jahnig. It is based on the observation that every second amino acid in a sided β-strand is either on average hydrophobic or hydrophilic. This means that one side of a β-strand is hydrophilic and faces the channel interior; the other side is hydrophobic and faces the lipid side chains. In addition to this simple approach, more sophisticated methods are also possible, such as secondary structure predictions based on a neural network-based predictor, which is suitable for finding β-sheets along protein sequences and is trained to recognize the topography of known bacterial β-strands. An example of this treatment is given in Fig. 10 for *N. crassa* porin. Within its primary sequence, 16 amphipathic β-strands (indicated by shaded boxes) can be recognized by this method. All studies of porin structure agree that the eukaryotic porins contain a high degree of antiparallel β-sheets as the main structural feature. The results of the secondary structure predictions are supported by CD measurements of eukaryotic porins. Native and recombinant porin from *N. crassa* shows, in these experiments, a high degree of β-sheet structure. In general, the recombinant porins seem to be a valuable model system for the study of eukaryotic porins by spectroscopic methods, in which high amounts of protein are needed. CD spectroscopy of root plastid porin was performed to determine the secondary structure of the protein under different conditions. It has a high degree of β-sheet structure in the nonionic detergent Genapol X-80 and in lipid vesicles. Although the presence of sterols is essential for reconstitution of eukaryotic porins in lipid bilayer membranes, the presence of sterols in the experiments with lipid vesicles does not change the CD spectra. The more polar detergent

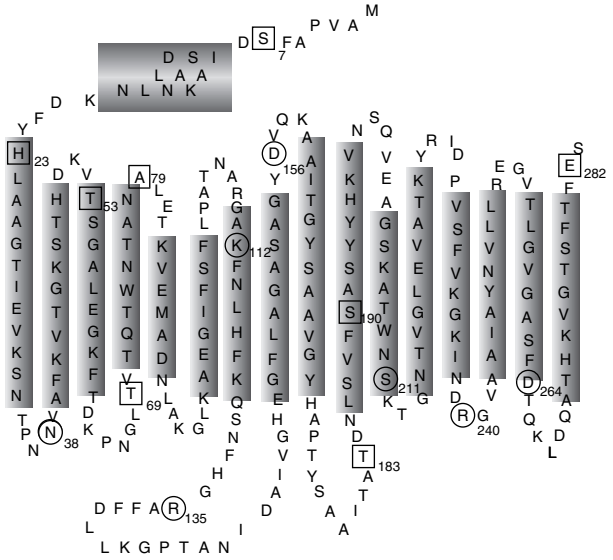

Fig. 10 Model of the arrangement of *N. crassa* porin in the membrane. The 16 putative β-strands are shaded in gray. Taken from Casadio, R., Jacoboni, I., Messina, A., De Pinto, V. (2002) A 3D model of the voltage-dependent anion channel (VDAC), *FEBS Lett.* **520**(1–3), 1–7 with permission.

SDS induces a large amount of α-helix structure in the protein. Similar results were obtained from experiments with two plant porin isoforms using attenuated total reflection Fourier-transform infrared spectroscopy (ATR-FTIR). Here, the β-sheet content of the eukaryotic porins was about 50%. Furthermore, the arrangement of the porins as detected by ATR-FTIR was very similar to that of OmpF of *E. coli*.

5.3
Structure of the Channel-forming Unit

Two different models of the channel-forming unit were derived from secondary structure predictions, site-directed mutagenesis, and deletion of part of the primary sequence of mitochondrial porins. One model assumes that the channel is composed of either 12 (yeast) or 13 (*N. crassa*) β-strands and the amphipathic N-terminal α-helix as part of the channel. This means that in the yeast model C- and N-termini of porin are on different sides of the membrane. It is, however, more likely that both are on the same side of the mitochondrial outer membrane because of the similarity to the situation in gram-negative bacteria, where they are at the periplasmic side of the outer membrane. According to the model, the amphipathic N-terminal α-helix resides in the lumen wall as part of channel gating. Its displacement by voltage should result in some sort of structural rearrangement of the pore, which leads to partial channel closure. Our own experiments with ΔN mutants of *N. crassa* porin (ΔN2–12porin and ΔN3–20porin) suggest that the N-terminus itself seems to be important for overall channel stability, rather than being directly involved in

gating. The gating characteristics of the ΔN channels were only slightly different from those of the wild-type channels, indicating that the structures responsible for the gating process are still intact in these mutants. This means that the N-terminus probably does not reside in the lumen wall of the mitochondrial outer membrane channel.

The second model assumes that the channel is formed by 16 antiparallel membrane-spanning β-strands, similar to the arrangement for general diffusion pores in the bacterial outer membranes. In this case, the amphipathic α-helix at the N-terminal end is localized within the surface of the membrane and exposed to the aqueous phase because it represents a major antigenic determinant of mitochondrial porins. These results suggest that the N-terminus is indeed localized in the surface of the membrane, most probably on the side of the intermembrane space of mitochondria; however, its possible role in channel gating remains open, but it may play a major role in channel stability (see below). Treatment of intact and broken bovine heart mitochondria with different proteases identified different cleavage sites of the pore-forming unit exposed to the aqueous phase and this was unchanged whether intact or broken mitochondria were exposed to the proteases. The cleavage sites are probably localized within surface-exposed loops of the protein. The C-terminal end may also be exposed to the surface, but it is not accessible to proteases because only a few amino acids may be localized outside the membrane. The C-terminus of *N. crassa* porin is clearly organized in antiparallel β-strands. The mutant that lacks 15 amino acids at the C-terminal (ΔC269–283porin) showed the same channel-forming activity as wild-type porin. It had a smaller single-channel conductance than wild-type protein, indicating a smaller channel size. However, its other biophysical properties, in particular, the voltage dependence, were identical to those of wild-type porin.

Figure 11 shows a model for *N. crassa* porin derived from neural network-based

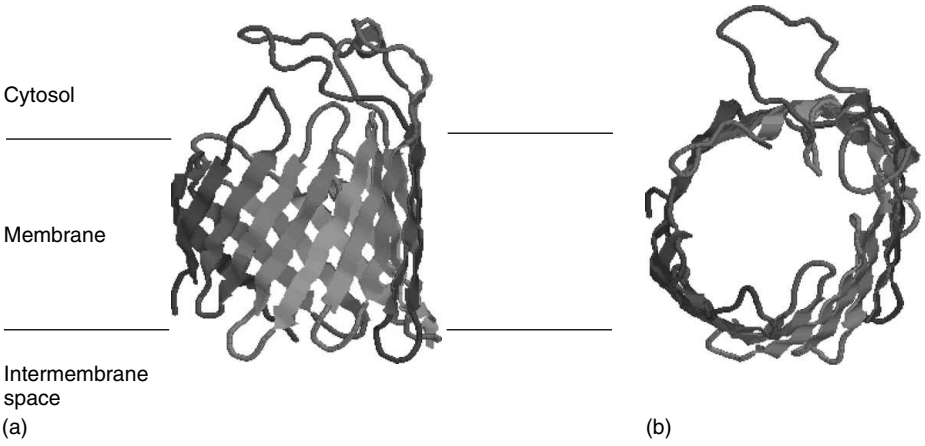

Fig. 11 Schematic view of the 3-D structure of the *N. crassa* porin. Note that the location of the N-terminus is not given. The coordinates were kindly provided by Rita Casadio and Vito De Pinto. (a) Side view. (b) View from the mitochondrial surface-exposed side.

predictors. The result of the prediction was compared to bacterial β-sheet proteins and used to align the primary sequence in coordinates of a three-dimensional (3-D) model. It is very similar to that proposed for yeast porin using the same formalism and has 16 antiparallel β-strands similar to the general diffusion porins of gram-negative bacteria. The model of *N. crassa* porin is shown in Fig. 11 ((a) from the side and (b) from the top). N- and C-termini are probably localized on the inner surface of the mitochondrial outer membrane (similar to the situation in gram-negative bacteria. The β-strands of *N. crassa* porin are tilted by about 40° to 60° similar to those of general diffusion pores. The loops connecting two β-strands are short on the internal surface of mitochondrial outer membrane and small at the opposite side. The hole is slightly oval and has a diameter of about 2.5 to 3 nm. The position of the amphipathic α-helical structure (not shown in Fig. 11) presumably represents a major problem for the validity of the model because it should somehow be involved in the stability of the pore as experiments with N-terminal deletion porins suggest. A simple, hollow β-stranded cylinder is presumably not stable in a membrane because of the lateral pressure in a lipid bilayer. It may result in a variation of its size as was shown for FhuA when the cork inside the β-barrel cylinder was removed. All known *β-stranded membrane channels* are somehow stabilized in their structure. External loop 3 stabilizes the bacterial porin channels. The α-hemolysin channel of *Staphylococcus aureus* is stabilized by the huge mushroom-like protrusion on the cis-side of the membrane and the receptors (for iron-siderophores or vitamin B12) are stabilized by the cork. A similar stabilizing element is also missing in both models for eukaryotic porins.

The model with 16 membrane-spanning β-strands appears to be more likely than that containing 13 (12) β-strands and the amphipathic N-terminus, although the latter model cannot be ruled out completely. The reasons for this can be summarized as follows:

- The porin channel is the primordial outer membrane channel and existed already when mitochondria evolved. Its overall structure may have been conserved, although there does not exist any homology between the primary structures of mitochondrial and bacterial porins. It has to be noted that homology between different bacterial porins can be very low, but the channel structure is well preserved.
- The amphipathic α-helix at the N-terminal end is the major antigenic determinant of eukaryotic porins, which means that it is probably not hidden inside the membrane.
- The results of experiments in which channel properties are changed by site-directed mutagenesis or by chemical modifications have to be taken with some care since the change of a single amino acid may induce a change that is related to a completely different region of the channel.

5.4
Are Sterols Involved in the Formation of the Channel-forming Unit?

Mitochondrial inner and outer membranes have different lipid compositions. The inner membrane contains cardiolipin, whereas sterols of different kind are exclusively found in the outer membrane dependent on the organism. Purified *N. crassa* porin contains the sterol ergosterol. Water-soluble mitochondrial porin from *N. crassa* that lost its associated

lipids and sterols needs sterols for functional reconstitution into lipid bilayer membranes. The detergent Triton X-100 plays a critical chaperone-like role in this process, similar to what has been found in the folding of bacterial porins. The role of different sterols was studied in the functional reconstitution of water-soluble porins from *Dictyostelium discoideum*, *Paramecium*, plant, and rat liver. The water-soluble porins regain their channel-forming ability after preincubation of the polypeptides with sterols in the presence of detergents. Some of the sterols can replace one another for channel formation, but influence channel gating. Interestingly, a sterol content of five cholesterol molecules per polypeptide unit was calculated in pig heart porin purified using the detergent LDAO. Sterols are probably not tightly bound to the polypeptide. The removal of sterols from the channel-forming complex may be responsible for the substantial loss of channel-forming activity during purification of mitochondrial porins.

5.5 Electron Microscopic Analysis of Mitochondrial Porin

Three-dimensional crystals of mitochondrial porin have not been obtained to date, which means that its tertiary folding structure is still not clear. However, it was possible to study 2-D crystals of fungal and recombinant human porin using electron microscopic analysis. Porin from *N. crassa* mitochondria crystallizes in periodic polymorphs with well-defined lattice parameters when outer membranes are subjected to phospholipase A2 treatment. According to the Fourier-filtered electron microscopic images of the crystalline arrays, the mitochondrial pore is a cylinder normal to the membrane plane with an outer diameter of about 3.8 nm for the hydrocarbon cylinder (the diameter of the polypeptide backbone is about 3.8 nm) and an inner diameter of about 2.5 nm. The crystalline arrays are composed of subunits that contain six porin channels. The lattice geometry responds to a number of external compounds. In particular, polyanion binds to the porin and leads to a substantial contraction of the lattice. Besides polyanion, apocytochrome *c* and the targeting sequence of an imported cytochrome oxidase subunit seem to bind to the periphery of the porin channel. More recently, 2-D crystals of *N. crassa* porin were analyzed using single-particle approaches. The results look promising, but it is not known yet if these approaches will lead to an improved resolution of porin structure. Human porin expressed in *E. coli* and reconstituted using detergent dialysis also forms 2-D crystals. The data derived from electron microscopic analysis of these crystals agree basically with those derived from 2-D crystals of *N. crassa* porin, but two neighboring molecules have opposite directions, which means that the 2-D crystals of human porin are not suitable for high-resolution imaging.

6 Conclusions

Eukaryotic porins form large water-filled channels in the ''open'' state with diameters around 2.5 to 3 nm that are slightly anion selective. The channels appear to be voltage-gated starting at about 20 to 30 mV and switch to ion-permeable closed states that are highly cation selective. Eukaryotic porins represent the major permeability pathway

of mitochondrial outer membranes, although porin-deficient mitochondria also exhibit oxidative phosphorylation. In addition to mitochondrial localization, there exists emerging evidence that other cellular compartments also contain eukaryotic porins with a yet unknown function. The first indication was the extramitochondrial location of porin 31HL, which is localized in the cytoplasmic membrane of a transformed human B-lymphocyte cell line. A similar channel is localized in astrocytic plasma membranes. Later, more evidence was found of such a location because a 36-kDa porin-like protein from rat brain copurified with the γ-aminobutyric acid/benzodiazepine receptor protein. It is possible that the channel from the astrocytic plasma membrane and the 36-kDa protein from rat brain relate to the ''maxi'' chloride channels present in the cell membrane of a number of eukaryotic cells. In excised patches, the channel has a maximum open probability at zero voltage, similar to the situation in lipid bilayer experiments.

The electrophysiological characterization of mitochondrial porin suggests that the permeability properties of the mitochondrial outer membrane could be voltage controlled. The generation of a voltage across the mitochondrial outer membrane is still open and it is not clear if the close apposition of inner and outer membranes *in situ* mitochondria is sufficient for electric coupling of both membranes and for channel gating. Furthermore, the exact mechanism of channel gating and the residues responsible for selectivity in the different states are completely open. In general, there exists some knowledge about the secondary structure of the eukaryotic porins. However, the precise 3-D structure, including the exact number of membrane-spanning β-strands and the diameter, are still unknown. Crystallographic data are badly needed to give clear answers to these questions and possibly also the localization of sterols in the channel-forming unit. Another open problem is the assembly of the porin channel. It is unlikely that it (i.e. the β-strands) forms inside a membrane since eukaryotic porins are polar proteins and are synthesized as water-soluble precursors outside membranes. This means that the channel is formed chaperone-promoted on the (inner?) surface of the mitochondrial outer membrane at a receptor site (Tom 20) from polypeptide and sterols. After formation, the channel inserts into the membrane using the general import pathway (TOM). So far it is not clear if it requires special insertion sites in the mitochondrial outer membrane or if the insertion process is similar to that in lipid bilayer membranes. In any case, it is likely that the channel is preformed before insertion. The preformation of channels in the aqueous phase or on the membrane surface is probably also the reason why lipid bilayer membranes represent a powerful tool for the study of mitochondrial and bacterial porins.

Acknowledgments

The generous supply of Figs. 10 and 11 by Rita Casadio and Vito De Pinto is gratefully acknowledged. I would like to thank Dieter Brdiczka, Vito De Pinto and Friedrich P. Thinnes for the fruitful and excellent collaboration during many years, and my collaborators Otto Ludwig, Birgit Popp, Elke Maier, and Angela Schmid for their excellent work with outer-membrane porins on which this review is largely based.

My own research was supported by the Deutsche Forschungsgemeinschaft (Project Be865/10) and by the Fonds der Chemischen Industrie.

Keywords

Axoneme
The core structure of the eukaryotic flagella and cilia composed of nine outer doublets of microtubule and a central pair of single microtubules, called ''9 + 2''.

Bacterial Flagellum
A long filamentous propeller rotated by a rotary motor used for bacteria swimming, composed of ~25 different proteins. Driven by ion flows through the motor part embedded in the cytoplasmic membrane.

Cilium
A short hairlike organelle found in many cells with almost the same structure with the eukaryotic flagella. Working for the transport of fluids over epithelial cells by a whiplike stroke. Some work as a sensor.

Dynein
A processive motor protein complex. Axonemal dynein generates the force of the eukaryotic flagellar and ciliary bending.

Eukaryotic Flagellum
A long filamentous organelle used for protozoan and metazoan sperm swimming, composed of highly organized microtubules and ~250 associated proteins. Showing a wavelike oscillatory motion generated by the dynein motor within the filament using the energy of ATP hydrolysis.

Flagellin
A structural protein forming the bacterial flagellar filament.

Intraflagellar Transport (IFT)
A system for transport of eukaryotic flagellar and ciliary components to the tip or base. Necessary for their assembly, disassembly, and maintenance. Driven by a kinesin motor to the distal tip (anterograde IFT) and a cytoplasmic dynen motor to the base (retrograde IFT).

Microtubule
A cytoskeleton composed of the dimer of α- and β-tubulin. Forming the core of the axoneme. Also associated with various cell activities, for example, mitosis, and so on.

MotA/B, PomA/B
An ion-driven torque generation unit for the rotation of the bacterial flagellum. MotA/B is a proton channel found in *Escherichia coli, Salmonella*, and so on. PomA/B is a sodium channel in alkaliphilic *Bacillus* and *Vibrio* species.

Type III Protein Export Apparatus
A protein complex for export of bacterial flagellar axial proteins into the cell exterior or virulence factors into host cells, driven by the energy of ATP hydrolysis.

Both eukaryote and prokaryote have flagella with a similar overall look, and use them for swimming in liquids, but they are completely different from each other. Cilia look like short hairs and have almost the same structure and mechanism as the eukaryotic flagella. The long filamentous structure of the eukaryotic flagellum is composed of highly organized microtubule-based structure and huge numbers of its associate proteins, while that in the bacterial flagellum is made of a single protein called *flagellin*. The length and the diameter of the filament in eukaryote are more than 10 times larger than those in bacteria. The total number of component proteins involved in the structure of eukaryote is also ~10 times of the prokaryote. The eukaryotic flagellum makes wavelike movements generated by the dynein motor within the filament using the energy of ATP hydrolysis, while the bacterial flagellum is a rotary motor driven by ion flows through the motor part embedded in the membranes. They both grow at their distal end, but use quite different mechanism for transport of their components to the distal tip.

Although the eukaryotic and bacterial flagella are complex macromolecules, recent studies are beginning to elucidate the roles of component proteins, their complex structures and growth mechanisms.

1 Eukaryotic Flagella and Cilia

Eukaryotic flagellum is a highly conserved organelle throughout protozoan to mammalian sperm. Its length is diverged in 10 to 200 μm, and the diameter is ~250 nm or more. The flagella show a wavelike oscillatory motion for swimming in fluid environments. Cilia are hairlike projections extended from the surface of various cells. They are not only shorter versions of the flagella but also work as systems for sensory perception of environments. In this article, we will not further discuss on these nonmotile cilia. Motile cilia show a whiplike stroke at 0.1 to 0.2 s per cycle for fluid transport over epithelial cells. For example, there are huge numbers of cilia in our respiratory tract. They sweep layers of mucus to transport trapped dusts and bacteria by their harmonic motions, up to the mouth where they are drunk or spewed out.

The motions of flagella and cilia are generated by bending of their internal cytoskeletal structure called the *axoneme*. The axoneme is composed of highly organized microtubules and their associated proteins, which include a motor protein complex, axonemal dynein. It generates the force for axoneme bending by utilizing the energy of ATP hydrolysis. In the axoneme, there are nine outer doublet microtubules surrounding the two single microtubules at its center, which

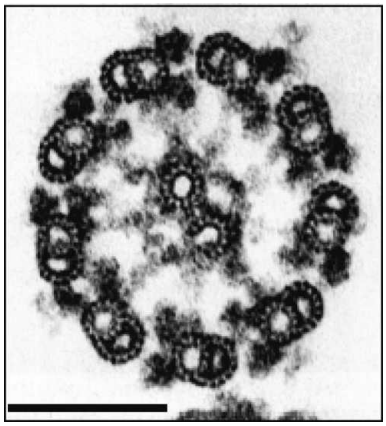

Fig. 1 Electron micrograph of a cross section of the flagellum from *Chlamydomonas*. Bar represents 100 nm (permission from Alberts, B., Johnson, A., Lewis, J., Raff, M., Roberts, K., Walter, P. (2002) *Molecular Biology of the Cell*, 4th edition, Garland Science, New York).

has been preserved for almost all eukaryotic flagella and cilia (Figs. 1 and 2). This characteristic structure is often called "9 + 2". A sensory cilium is an exception, which lacks the two central microtubules, and so-called "9 + 0". The base structure known as the basal body also shows a complicated structure, composed of nine triplets of microtubules without the central pair (Fig. 3). The basal body is critically important for constructing the axoneme. *Chlamydomonas*, a green alga, has two motile flagella at the anterior end of the cell. Recent studies especially on this alga have explored its huge number of constituent molecules and have begun to reveal the growth mechanism of the flagella and cilia.

1.1 The Axoneme

The axoneme has a huge complex structure composed of ~250 different proteins, which include cytoskeletal proteins, motor proteins, molecular chaperons, calcium-binding proteins, protein kinases, and so on. However, more than half of them have not yet been characterized. In general, the component proteins are well conserved among the flagella of protozoan and metazoan sperm, except for some components. Figures 1 and 2 shows a typical electron micrograph and a schematic diagram of a cross section of the axoneme.

1.1.1 Microtubule

Microtubules form the core 9 + 2 structure in the axoneme. Nine outer doublet microtubules are arranged in a ring around the central two microtubules (Figs. 1 and 2). Each of the outer doublets is made of a complete tube called *A-tubule* and a partial tube called *B-tubule*, fused together. This characteristic design has been unchanged throughout protozoan to mammals. The structural unit of microtubule is a hetero dimer of α- and β-tubulin, which share ~40% sequence homology. α- and β-tubulin are evolutionally well-conserved molecules comprising ~450 residues. The atomic model of the dimer was first determined by electron crystallography on zinc-induced two-dimensional sheets, in which the dimers form a regular array.

α- and β-tubulin show very similar folds, having two β-sheets made of 4 and 6 strands, flanked by 12 α-helices. They have a typical Rossman fold for nucleotide binding at their N-terminus,

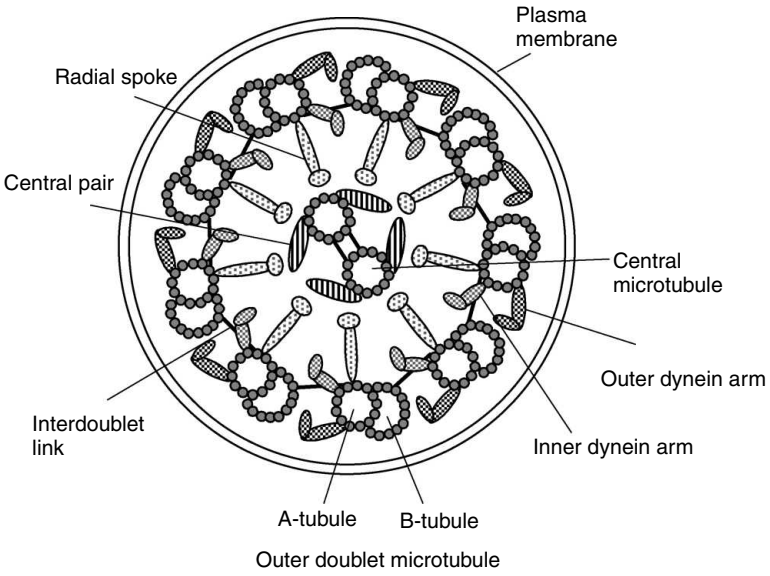

Fig. 2 Cartoon of the cross section of the flagellum or the cilium shown in Fig. 1.

where unexchangeable GTP is tightly bound in α-tubulin and exchangeable GTP or GDP is bound in β-tubulin. The dimers form a protofilament by connecting α-tubulin of one dimer to β-tubulin of another. The nucleotide binding sites of β-tubulin is placed at the interface of the dimers along the protofilament. A-tubule is a cylindrical hollow structure built of 13 protofilaments, while B-tubule is made of 11 protofilaments. Because all the protofilaments are oriented in parallel, one end of microtubule is occupied by all α-tubulin and the other end by all β-tubulin. The end made of α-tubulin is called the *minus end* and that made of β-tubulin is called the *plus end*. Microtubule assembles or disassembles $\sim$100 times faster from the plus end than the minus end. Whether the β-tubulin molecules at the plus end bind GTP or GDP affects the assembly and disassembly; GTP promotes assembly, while GDP promotes disassembly. In general, the GTP-bound filament becomes straight and stiff, while the GDP-bound one tends to be curved and unstable.

In the zinc-induced two-dimensional sheets, the protofilaments are arranged in an antiparallel fashion. Hence, details of the lateral interactions between the protofilaments in microtubule are not yet clear, although the same kinds of molecules are known to make major lateral contacts, such as $\alpha-\alpha$ or $\beta-\beta$. α- and β-tubulin form a complete microtubule *in vitro*, while they never form a doublet microtubule, as found in the axoneme. This requires the basal body and other associated proteins described below.

1.1.2 **Axonemal Dynein**

Dynein is a microtubule-specific motor protein complex that consumes ATP for force generation. The dynein family is divided into two major groups: cytoplasmic dynein and axonemal dynein. Axonemal dynein is a huge molecular complex with a molecular mass of $\sim$2 MDa and is involved

in the motility of eukaryotic flagella and cilia. In the axoneme, a pair of dynein ''arms'' with a dimension of ~25 nm are projected from A-tubule to form bridges with B-tubule of the adjacent outer doublet microtubule (Fig. 2). They are placed at a regular interval of ~24 nm along A-tubule. The arms projected inside and outside the ring of the microtubule doublet are called the *inner* and *outer dynein arms* respectively. When the motor is activated, the dynein molecules try to ''walk'' along the adjacent B-tubule just as myosin molecules slide along the actin filament on muscle contraction. However, owing to the interdoublet links (see below) among the outer doublets, the walking motion is converted to bending of the cilium or the flagellum.

The outer dynein arm consists of two heavy chains, three to five intermediate chains, and six light chains in metazoan sperm, and is made of three heavy chains, two intermediate chains, and eight light chains in *Chlamydomonas*. Dynein heavy chains are huge proteins with molecular masses of ~500 kDa, and act as the fundamental motor unit. They contain a globular head with ATPase activity and a microtubule-binding stalk. The globular head shows a ringlike structure made of six subdomains, each of which corresponds to AAA (ATPase Associated with various cellular activity) domains. Four of the six AAA domains have P-loop for ATP binding. There is a coiled-coil domain between the 4th and 5th AAA domains, which is thought to be essential for ATP-sensitive binding to the adjacent B-tubule. Domain between each AAA domain seems to be important for conformational changes necessary for the dynein power stroke. Dynein intermediate chains are 120- to 60-kDa proteins, and are presumably necessary for binding on A-tubule. Dynein light chains are 30- to 8-kDa proteins, and might be a regulator for activation of the outer dynein arm.

The inner dynein arm has more complicated molecular compositions than the outer dynein arm. It contains multiple molecular species with more heavy chains.

1.1.3 The Radial Spoke and the Central Pair

The radial spoke and the central pair (Fig. 2) are composed of a large number of proteins as well, and some of them include a domain that anchors cAMP-dependent protein kinase and a calcium binding domain. Therefore, the radial spoke presumably regulates the inner dynein arm through phosphorylation/dephosphorylation and calcium-dependent changes in the flagellar waveform. The central pair probably determines the plane of bending of the flagellum by sending signals to the radial spoke.

1.1.4 Other Proteins Associated with the Axoneme Structure

The interdoublet link (Fig. 2) known as the ''nexin'' linkage is thought to hold the outer doublet microtubules together and prevent their mutual sliding by the power stroke of the dynein arms.

Fibrous proteins called *tektin* presumably connect with the interdoublet links and support the ninefold symmetry architecture of the axoneme. Chaperons homologous to HSP70 are associated with this fiber. Also, another chaperon, HSP40, is identified as an axonemal component. These chaperons might help the folding of newly transported proteins through the intraflagellar transport described below.

Proteins related to determine a regular 24-nm interval of the outer dynein arms have also been identified and are called the *outer dynein arm docking complex*. They

are predicted to have a coiled-coil structure and may work as a molecular scale.

1.2 The Basal Body

In the root of the cilia and flagella, there is a cylindrical structure called *the basal body*. The basal body has another characteristic structure constructed from nine sets of triplet microtubules (Fig. 3). The triplets are tilted inward and are connected to the neighbors as well as to the radial spokes extended from the central core, forming a pinwheel-like structure. Each triplet comprises one complete microtubule (A-tubule) fused to two partial microtubules (B- and C-tubule). The basal body has the same structure as centrioles, which are embedded in the center of mitotic spindles known as *centrosomes*. Indeed, the basal body of sperms and flagella is converted to the centriole during fertilization in mammals and mitosis in *Chlamydomonas* respectively. The basal body and the centriole are duplicated from its origin so as to form a smaller daughter perpendicular to the origin. In *Chlamydomonas*, specialized microtubule bundles called *rootlet microtubules* are known to be involved in positioning the daughters, but little is known about the replication mechanism.

The basal body is essential for the assembly of the cilia and the flagella. It not only serves as a template for organization of the nine doublet microtubules of the axoneme but also incorporates huge numbers of proteins involved in the intraflagellar transport (see below). A recent electron tomographic study revealed various cross sections of the basal body along the central axis and transition zones to the axoneme (Fig. 4). The basal body starts from an amorphous disk at its proximal end (Fig. 4-1) and then continues to the pinwheel-like structure made of the nine triplets (2 and 3). It extends to ~40 nm in length, and then becomes the distal transitional fibers with striated structures, which end on the plasma membrane (4). There are stellate fibers in the transition zone associated with the loss of the C-tubule (5 and 6). At the end of the stellate fibers (7 and 8), the central pair of microtubules appears along with additional axonemal structures (9).

The basal body assembly also needs over 200 distinct proteins, whose roles are being characterized. A member of the tubulin

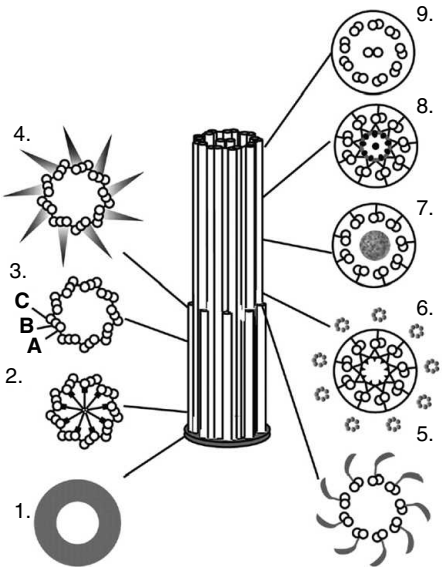

Fig. 4 Structural organization of the basal body, transition zone, and flagellum. Cross sections (1–9) are displayed from proximal to distal, respectively. Permission from O'Toole, E.T., Giddings, T.H., McIntosh, J.R., Dutcher, S.K. (2003) Three-dimensional organization of basal bodies from wild-type and δ-tubulin deletion strains of *Chlamydomonas reinhardtii, Mol. Biol. Cell.* **14**, 2999–3012.

super family, γ-tubulin, which is ~30% identical to α- and β-tubulin, is involved as an essential factor. Microtubules are nucleated at their minus end, but the concentrations of α- and β-tubulin inside the cells are below those required for spontaneous nucleation *in vitro*. Therefore, in all eukaryotes, the assembly of microtubules requires γ-tubulin. γ-tubulin is attached at the minus end of microtubules, forming a microtubule-organizing center (MTOC) together with other associated proteins. The basal body also includes other members of the tubulin super family, δ-, ε-, ζ-, and η-tubulin, which are probably required for construction of the basal body and formation of the axoneme.

1.3 The Intraflagellar Transport

The eukaryotic flagella and cilia grow at their distal tip. Components synthesized in the cytoplasm are transported through a system known as the *intraflagellar transport* (IFT). IFT was identified only a decade ago as particles rapidly moving (2–4 μm/s) within the flagella of *Chlamydomonas*. This movement has been recognized to be essential for the growth, maintenance, and shortening of the cilia and flagella in all eukaryotes.

IFT consists of bidirectional movement of large protein particles along the outer doublet microtubules. Particles called the *IFT particles* are transported to the distal end (anterograde IFT) at ~2 $\mu m\, s^{-1}$ by a motor protein, kinesin II, and back to the cell (retrograde IFT) at ~4 $\mu m\, s^{-1}$ by a cytoplasmic dynein. Kinesin II is a member of the kinesin super family, which, in general, proceeds toward the plus end of microtubule, but is unrelated to dynein, which proceeds toward the minus end. The IFT particles work as a raft to carry components of the axoneme and form large linear arrays up to several hundred nanometers long. They can be divided into two complexes known as "A and B". Complex A is composed of four to six subunits with an apparent molecular

mass of ~550 kDa, and complex B is made of at least nine subunits with a molecular mass of ~750 kDa. Complex A and B seem to be associated with retrograde IFT and anterograde IFT respectively.

IFT never stops and keeps moving at the same speed when the flagellum reaches its full length. Also, the IFT particles are remodeled at the base and the distal tip of the flagellum. Therefore, cells could regulate the assembly or disassembly of the flagellum by changing loads of the IFT particles at the base or the tip.

1.4 Perspectives

The eukaryotic flagella and cilia show a characteristic structure made of microtubules and ~250 associated proteins, half of which have not been characterized yet. Different from the bacterial flagella (see below), they have adopted a widely used system, the dynein motor for the force generation. Microtubule-dependent motors are also used for the process known as *IFT*, for growth, maintenance, and shortening of the cilia and flagella. Extensive studies, especially on the *Chlamydomonas* flagella, have just started to identify the roles of each protein and the growth mechanism. However, there are still too many unknowns. High-resolution structural information would be essential for further understanding of this system, and electron microscopy would be one of the most powerful tools to explore the structures and mechanisms of this complicated organelle.

2 Bacterial Flagella

Many bacteria swim by rotating helical flagellar filaments, which grow up to ~15 μm. The motor at the base of the filament drives the rotation of this helical propeller at hundreds of revolutions per second. In *Escherichia coli* and *Salmonella*, proton flow through the cytoplasmic membrane is utilized for the rotation. For chemotaxis and thermotaxis, the swimming pattern of bacteria alternates between ''run'' and ''tumble''; a run lasts for a few seconds and a tumble for a fraction of second. During a run, the motor rotates counterclockwise (as it is viewed from outside the cell), and several flagellar filaments with a left-handed helical shape form a bundle and propel the cell. A tumble is caused by quick reversal of the motor to clockwise rotation, which produces a twisting force that transforms the left-handed helical form of the filament into a right-handed one, causing the bundle to fall apart rapidly. The separated filaments act in an uncoordinated way to generate forces that change the orientation of the cell. This leads to the tactic behavior, moving toward favorable or away from unfavorable conditions. Thus, the structure of the flagellar filament and its dynamic properties play an essential role in bacterial taxis.

The bacterial flagellum consists of several substructures. The motor structure called the *flagellar basal body* crosses both cytoplasmic and outer membrane, and continues to the extracellular structure called the *hook* and the *filament*. The largest of all is the filament, which is only ~20 nm in diameter, but grows up to a length around 15 μm by self-assembly of as many as 20 000 to 30 000 flagellin subunits. The assembly of the flagellum proceeds in a highly regulated fashion by the type III flagellar protein export apparatus, and flagellar axial proteins are always incorporated into its distal end, where capping proteins

help the assembly in most cases. The bacterial flagella are best understood in terms of the structure and function for those of *E. coli* and *Salmonella typhimurium*, because much of relevant work has been carried out using them. Overall structure of the bacterial flagellum is shown in Fig. 5.

2.1 Component Structures

2.1.1 The Basal Body

The basal body of the bacterial flagellum consists of the MS ring (also called *FliF ring*), the C ring, the rod, and the L–P ring.

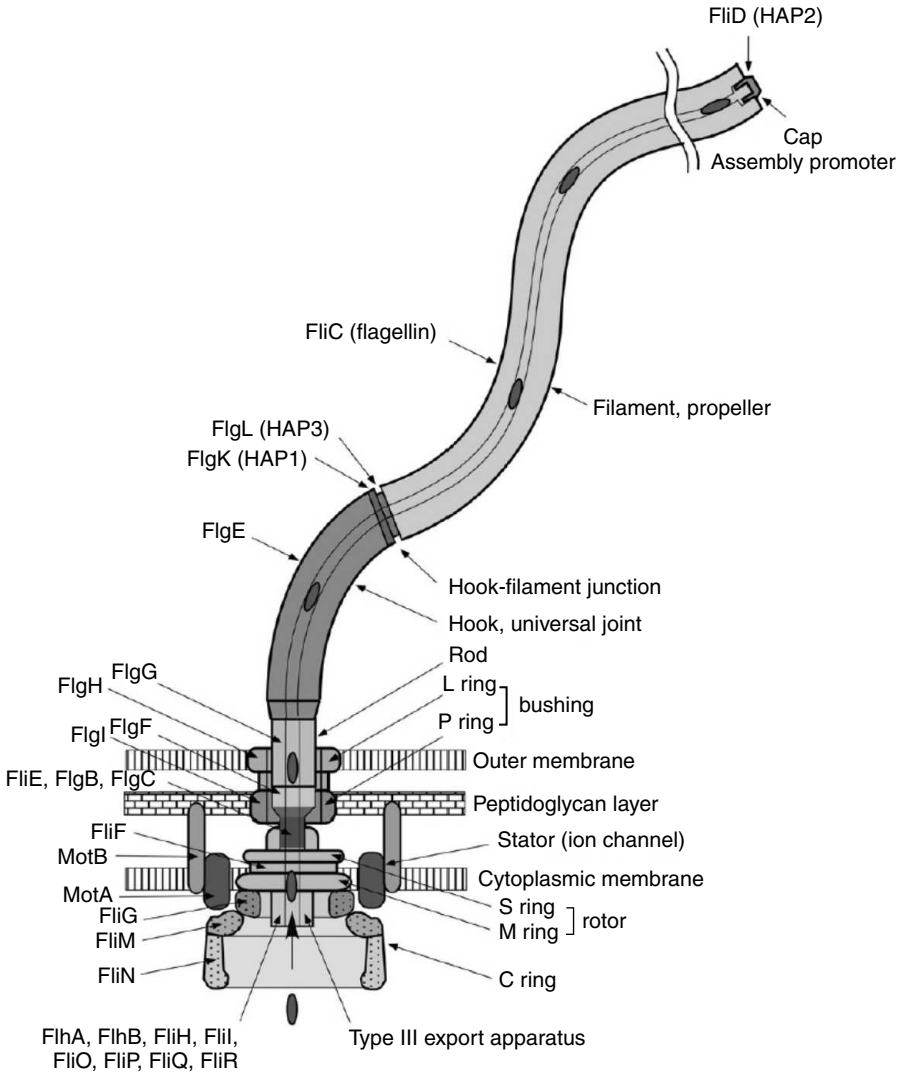

Fig. 5 Schematic diagrams showing the architecture of the bacterial flagellum. Reproduced with permission from Namba, K., Vonderviszt, F. (1997) Molecular architecture of bacterial flagellum, *Q. Rev. Biophys.* **30**, 1–65.

The MS ring with a diameter of ~250 Å is made of ~26 copies of FliF protein arranged cylindrically in the cytoplasmic membrane. ''MS'' means membrane and supramembrane. The C ring, a large cup-like structure attached on the cytoplasmic surface of the MS ring, is made of FliG, FliM, and FliN. ''C'' stands for cytoplasm. The rod, which traverses through the periplasmic space and the outer membrane, is made of FliE, FlgB, FlgC, FlgF, and FlgG proteins and is attached to the periplasmic face of the MS ring. The L–P ring is made of FlgH and FlgI, which are located within the outer membrane and the peptidoglycan layer respectively. L–P means ''lipopolysaccharide'' and ''peptidoglycan.'' The MS ring is the base for self-assembly of all the flagellar proteins to form the flagellum and is partly involved in the type III flagellar protein export mechanism. The C ring is involved in torque generation as well as in regulation of its direction. The rod transmits the motor torque to the extracellular structures such as the hook and filament. The L–P ring is a bushing that mechanically supports the rapid rotation of the flagellum.

2.1.2 The Motor

Two cytoplasmic membrane proteins, MotA and MotB, are responsible for torque generation of the flagellar motor. MotA and MotB have four and one transmembrane-spanning helices respectively, and together form a proton channel. The MotA/B complex also functions as the stator by being attached to the peptidoglycan layer of the cell through a binding motif in the periplasmic domain of MotB. Electron micrographs of freeze-fractured samples showed that the stator complexes appear as a circular array of particles on the cytoplasmic membrane, surrounding the MS ring.

Some bacteria, such as alkaliphilic *Bacillus* and *Vibrio* species, normally have only one flagellum at their cellular pole, and use the electrochemical potential of sodium ions to generate the torque. The maximum rotational speed of the sodium-driven motor is ~1700 Hz, while that of the proton-driven motor is ~300 Hz. Four proteins, PomA (POlar flagellar Motility A), PomB, MotX, and MotY have been identified and are shown to be necessary for the rotation of the polar flagellar motor of *Vibrio*, such as *V. alginolyticus*, *V. parahaemolyticus*, and *V. cholerae*. PomA and PomB are homologous to MotA and MotB, while MotX and MotY are unique to the sodium-driven motor of *Vibrio*. Although the functions of MotX and MotY are not yet clear, a recent study showed that they are located in the outer membrane, and suggested that they may be essential for sodium recognition and for fast rotation of the polar flagellum.

For torque generation, MotA/B and PomA/B are thought to undergo a conformational change coupled to the proton flow and sodium flow, respectively while they interact with FliG, which is a component of the C ring. The X-ray crystal structures of the C-terminal and middle domains of FliG have revealed that important charged residues are lined up on one side of FliG so as to interact with a cytoplasmic loop of MotA or PomA. The functional unit of the motor complex is thought to be 4 MotA/2 MotB or 4 PomA/2 PomB.

2.1.3 The Hook and the Hook-filament Junction

The hook is a tubular structure, continuing directly from the rod into the outside of the cell. It is ~55 nm long and ~180 Å wide, and is made of ~120 copies of

FlgE, which is also called the *hook protein*. The hook and the filament are connected with a short segment composed of two proteins, FlgK (also called *hook-associated protein 1* or HAP1) and FlgL (HAP3). Because the hook shows a relatively high flexibility in bending, it probably works as a universal joint to transmit the torque to the filament in a wide range of its orientation, thereby allowing several filaments to form a bundle behind the cell during run as well as to rotate individually during tumble.

2.1.4 The Flagellar Filament

The flagellar filament is a helical assembly of a single protein, flagellin, with roughly 5.5 subunits per one turn of the 1-start helix. The filament can also be described as a tubular structure comprising 11 protofilaments, which are nearly longitudinal helical arrays of subunits. Left- and right-handed helical forms of the filament are produced by supercoiling caused by mixture of two distinct protofilament conformations, L- and R-type. When all of the 11 protofilaments are the same type, two types of straight filaments with distinct helical symmetries are formed: The longitudinal 11-start helix is left-handed in the L-type and right-handed in the R-type straight filament.

The structures at ~10 Å resolution by earlier studies using electron microscopy and X-ray fiber diffraction revealed the subunit shape, domain organization, and subunit packing in these two types of straight filaments. However, higher resolution was needed to understand the structural mechanisms of the filament formation and supercoiling in atomic detail. Flagellin has a strong tendency to polymerize into filaments and this has prevented its crystallization. By clipping off terminal chains for ~100 residues in total, a fragment named "F41" was crystallized, and its structure was solved at 2.0 Å resolution by X-ray crystallography. Recently, the complete atomic model of the R-type straight flagellar filament was built on a density map at ~4.0 Å resolution obtained by electron cryomicroscopy and helical image reconstruction.

Flagellin from *S. typhimurium* SJW1103 strain consists of 494 amino acid residues, and its molecular mass is 51.5 kDa. Flagellin in Fig. 6 is viewed perpendicular to the filament axis. The overall shape of flagellin looks like a Greek letter "Γ" with a vertical dimension of ~140 Å and a horizontal dimension of ~110 Å. Flagellin consists of four linearly connected domains labelled D0, D1, D2, and D3, which are arranged from inside to outside of the filament (Fig. 7a). The N-terminal chain starts from D0, going through D1, D2, and reaches D3, and then comes back through D2 and D1, and the C-terminal chain ends in D0. While all three domain connections are formed by pairs of short antiparallel chains, the one that connects domains D0 and D1 is longer than the other two, and therefore it is called the *spoke region*. The top and the bottom correspond to the distal and proximal side of the flagellum respectively. We also define the distal side "up" and proximal side "down," and describe the structure accordingly.

Domain D0 consists of the N- and C-terminal α-helices forming an α-helical coiled-coil structure (labelled ND0 and CD0 respectively in Fig. 6a). The spoke region consists of two chains (NS and CS), which connect to two α-helices in domain D1 (ND1a and CD1). Helix ND1a is followed by a loop connecting to the second, shorter α-helix (ND1b), which goes down, and the chain continues to two β-turns, a β-hairpin pointing down and an extended chain going up. The chain

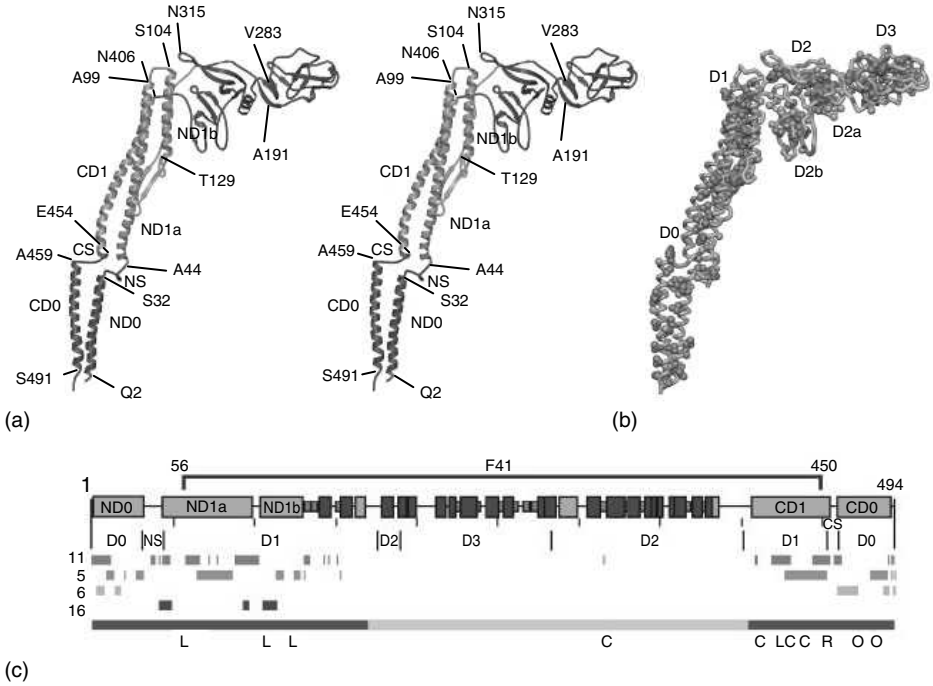

Fig. 6 The Cα backbone trace, hydrophobic side-chain distribution, and structural information of flagellin. (a) Stereo diagram of the Cα backbone. The chain is color coded as follows: residues 1 to 44, blue; 44 to 179, cyan; 179 to 406, green; 406 to 454, yellow; 454 to 494, red. (b) Distribution of hydrophobic side chains, mainly showing hydrophobic cores that define domains D0, D1, D2a, D2b, and D3. Side-chain atoms are color-coded: Ala and Met, yellow; Leu, Ile, and Val, orange; Phe, Tyr, and Pro, purple (carbon) and red (oxygen). (c) Position and region of various structural features in the amino acid sequence of flagellin. Shown are, from top to bottom, the atomic model of a major fragment of flagellin called F41 in blue; the secondary structure distribution with α-helix in yellow, β-structure in green, and β-turn in purple; tic mark at every 50th residue in blue; domains D0, D1, D2, and D3, and spoke regions NS and CS; the subunit contact regions along the 11-start in cyan, along the 5-start in orange, along the 6-start in pink, and along the 16-start in green; the well-conserved amino acid sequence in red and variable region in violet; point mutations that produce the filament of different supercoils. Letters at the bottom indicate the morphology of mutant filaments: L (F53V, D107E, R124A, R124S, G426A), L-type straight; R (A449V), R-type straight; C (D313Y, A414V, A427V, N433D) curly; O (Q472L, Q481L, Q481S) coiled. Permission from Yonekura, K., Maki-Yonekura, S., Namba, K. (2003) Complete atomic model of the bacterial flagellar filament by electron cryomicroscopy, *Nature* **424**, 643–650. (See color plate. p. xxvii)

finally goes into the outer parts, domain D2 and D3, which are mainly composed of β-structures. The vertical dimensions of domain D0 and D1 are ~50 Å and 80 Å respectively. The extended chains in the spoke region are ~20 Å long.

The end-on view of the R-type straight filament from the distal end of the flagellum (Fig. 7a) shows the concentric double-tubular structure made of domains D0 and D1 in the densely packed filament core. Domains D2 and D3, which project

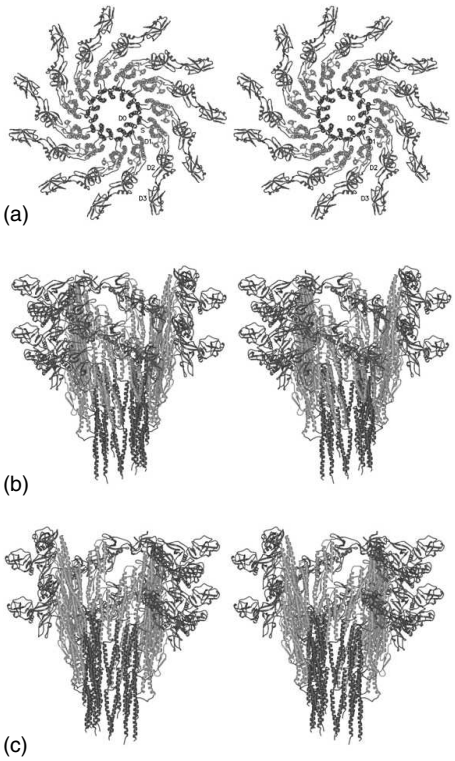

Fig. 7 Ribbon diagram of the Cα backbone of the filament model in stereo view. (a) End-on view from the distal end of the filament. Eleven subunits are displayed. (b) Side view from outside the filament. Three protofilaments on the far side have been removed for clarity. (c) Side view from inside the filament. Three protofilaments on the near side have been removed. Top and bottom of the side view images correspond to the distal and proximal ends of the filament respectively. The chain is color coded as in Fig. 6(a). Permission from Yonekura, K., Maki-Yonekura, S., Namba, K. (2003) Complete atomic model of the bacterial flagellar filament by electron cryomicroscopy, *Nature* **424**, 643–650. (See color plate. p. xxiii)

out from the filament core, are relatively well separated from one another. The diameter of the filament is ~240 Å and that of the central channel is ~20 Å. The N- and C-terminal α-helices (ND0 and CD0) are radially arranged with ND0 outside and CD0 inside, exposed to the central channel. The chains connecting domains D0 and D1 (NS and CS) look exactly like radial spokes in this view. As shown in side views from outside and inside the filament (Figs. 7b and 7c), domains D0 and D1 are making intimate intersubunit interactions, both axially and laterally. As a polar assembly of flagellin having a largely asymmetric structure, the filament model shows the concaved feature at the distal end (top of Fig. 7c) and the pointed tip at the proximal end (bottom), which are observed even in electron micrographs of negatively stained filaments. The terminal chains of ~65 N-terminal and 45 C-terminal residues are unfolded in the monomeric form of flagellin in solution. It can be inferred from this structure that, in the absence of axial and lateral packing interactions of these terminal chains in the inner tube, the two-stranded α-helical coiled coil in domain D0 with relatively less extensive hydrophobic core and a pair of extended, rather flexible looking chains connecting to domain D1 would be highly unstable. In contrast, the upper two-thirds of domain D1 can form its compact tertiary structure in the monomeric form because of its extensive hydrophobic core formed by three α-helices and one β-hairpin. The outer parts of flagellin are variable so that bacteria can escape from the attacks of host immune system, while the core

part consisting of domains D0 and D1 are highly conserved (Fig. 6c).

The interactions within the inner and outer tubes are extensive, both along and between the protofilaments, while those between the inner and outer tubes are limited and are mainly in the spoke region. Most of the intersubunit interactions found within the outer tube are polar–polar or charge–polar, and contributions of hydrophobic interactions are relatively small, whereas those found within the inner tube and between the inner and outer tubes are mostly hydrophobic, contributing to the high stability of the filament structure.

There are heptad repeats of hydrophobic amino acid residues in the terminal regions of flagellin as well as other axial components, such as FlgE, HAP1, HAP3, and so on. In the filament structure, the terminal chains of neighboring subunits fold together into α-helical coiled coils. This interlocking organization would be the common motif by which the flagellar axial proteins form a continuous, mechanically stable tubular structure. The needle structures of the type III protein export system (see below) of pathogenic bacteria used to inject virulence proteins into host cells are genetically related to the bacterial flagellum, and are thought to have α-helical coiled coil as a common motif as well.

The atomic structure of the R-type straight filament has also revealed interactions of mutation sites responsible for polymorphic supercoiling of the filament. However, the true understanding of the mechanism of polymorphic supercoiling and its dynamic transition has to wait until the atomic model of the L-type straight filament becomes available.

2.1.5 **The Filament Cap**

The distal end of the bacterial flagellum shows a thin, flat plate structure as identified by electron microscopy. This flat plate is a part of the filament cap made of HAP2 subunits. HAP2 from *S. typhimurium* is composed of 466 amino acid residues, and its molecular mass is 49.8 kDa. HAP2 forms a decameric complex in solution. The decamer shows a pentameric feature in its end-on view and a bipolar structure with two thin plates on both edge connected by a pair of long, slightly tapered cylindrical walls in its side view. The connecting portion appears to be relatively flexible. Figure 8

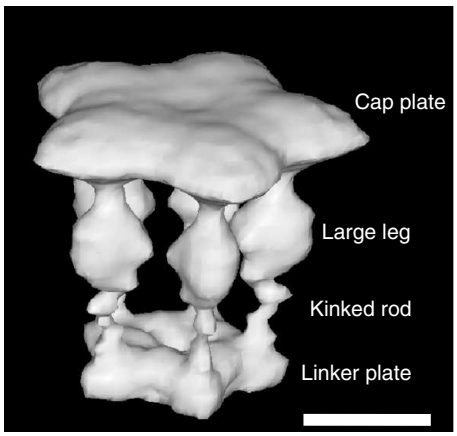

Fig. 8 Reconstructed three-dimensional image of the HAP2 pentamer. Bar represents 50 Å. Permission from Maki-Yonekura, S., Yonekura, K., Namba, K. (2003) Domain movements of HAP2 in the cap-filament complex formation and growth process of the bacterial flagellum, *Proc. Natl. Acad. Sci. U.S.A.* **100**, 15528–15533.

shows the three-dimensional structure of the HAP2 cap reconstructed from electron cryomicrographs. The HAP2 cap is composed of a pentagonal plate and five leg domains, whose lower part has no particular feature. This portion is made of both terminal regions of HAP2, because when ~40 N- and 50 C-terminal residues of HAP2 are cleaved off, the fragment does not form the decamer. These terminal chains are disordered in the pentameric or monomeric form of HAP2, suggesting that they also have the common structural motif shared by the flagellar axial proteins to form α-helical coiled coil in the inner core of the tubular structure. The heptad repeats are actually identified in the amino acid sequence of these terminal regions.

2.2 The Assembly Process of the Bacterial Flagellum

The assembly process of the bacterial flagellum starts from the formation of the MS ring complex in the cytoplasmic membrane. Then, the C ring is formed on the cytoplasmic face of the MS ring. The type III protein export apparatus, which is homologous to those that enable pathogenic bacteria to secret virulence factors, is presumably formed within the C ring. The export apparatus is composed of six membrane proteins and several cytoplasmic proteins (see below). The torque generation unit MotA/B assembles around the MS ring and is anchored to the peptidoglycan layer with the periplasmic domain of MotB. Each flagellum probably has about eight torque generation units.

The outward assembly of the flagellar axial structures proceeds at the distal end as it was initially found for the filament growth. The L–P ring assembly is an exception, where the subunit proteins FlgH and FlgI assemble around the rod in the outer membrane and peptidoglycan layer respectively. These proteins are exported by a general secretion system known as the *Sec pathway*. The formation of the P ring needs a periplasmic chaperone, FlgA. The type III protein export apparatus selectively binds and translocates flagellar axial proteins into the central channel of the growing flagellum by using the energy of ATP hydrolysis by FliI (see below). The axial proteins construct the rod, the hook, the hook-filament junction, and the long filament in this order. The proximal rod components FliE, FlgB, FlgC, and FlgF are connected with the periplasmic side of the MS ring, probably in this order, and the distal rod component FlgG follows to assemble. The rod assembly requires a help of the rod cap made of FlgJ, whose C-terminal domain has a muramidase activity to digest the peptidoglycan layer and to promote the rod growth through it. After the rod assembly is completed, the rod cap is somehow released, and FlgE assembles on the distal end of the rod in a helical manner to form the hook. A cap complex made of FlgD is attached at the distal end of the hook for its efficient assembly until it grows up to a length of ~55 nm. The length of the hook is controlled by FliK, one of the rod/hook-type export substrates, and FlhB, a member of the export apparatus (see below). A relatively short C-terminal region of FliK interacts with the cytoplasmic domain of FlhB at an appropriate timing to switch its conformation, resulting in the switching of substrate specificity of the export apparatus from the rod/hook type to the filament type (see below). This is how the hook growth stops, but the detailed mechanisms as to how the hook length information is transmitted to the cytoplasmic domains of the export apparatus is not yet well understood. Recent studies suggest

that FliK acts as a ruler, but an alternative hypothesis called the *measuring cup mechanism*, in which 120 copies of FlgE are measured by the C-ring, may also be valid.

Then, the hook cap falls off the tip of the hook, probably by the binding of FlgK (HAP1), and then FlgL (HAP3) and FliD (HAP2) are transported and bound at the distal end in this order. FlgK, FlgL, and FliD are also called hook-associated proteins, HAP1, HAP3, and HAP2 respectively, because the hook-HAP1-HAP3-HAP2 complex is formed momentarily before the initiation of flagellin assembly into the long helical filament. Flagellin, also called ''FliC'', travels a long way through the narrow tunnel, only ~20 Å in diameter, but up to 10 to 15 μm long, to the distal end of the growing flagellum, where it assembles with a helical symmetry into the mechanically stable filamentous structure to function as a helical propeller. The filament cap made of HAP2 is always attached at the distal end, promoting the efficient assembly process.

2.2.1 The Type III Protein Export Apparatus

Most of the flagellar axial proteins are exported by the type III protein export apparatus into the central channel and to the distal end. The flagellum-specific secretion apparatus is made of six membrane proteins (FlhA, FlhB, FliO, FliP, FliQ, and FliR) and two soluble proteins, FliH and FliI. FliI has an ATPase activity and acts as the engine of export.

In addition to those, there are a general chaperon, FliJ, and substrate-specific chaperons, FlgN, FliS, and FliT, which bind to the export proteins synthesized in the cytoplasm and prevent them from undesirable aggregation or digestion, and from premature assembly within the cell. The partners of the substrate-specific chaperons are as follows: FliS–FliC; FlgN–FlgK; FlgN–FlgL; and FliT–FlgD. The structure of a complex of FliS with a short fragment of flagellin was recently solved by X-ray crystallography. This fragment corresponds to the C-terminal ~40 residues, which forms helix CD0 in the filament (Figs. 6 and 7). In the crystal structure of the complex, this helix is bent in the middle and partly extended, so as to keep the hydrophobic residues away from solution. FliS would prevent flagellin from forming the filament in this manner.

The flagellar type III protein export apparatus also specifies the order of the export substrate proteins. A recent study shows that there are two clear modes; the rod-type (FliE, FlgB, FlgC, FlgF, and FlgG) and the hook-type (FlgD, FlgE, FliK) proteins are exported in one mode, and the filament-type proteins, including FlgK, FlgL, FliD, and FliC, are exported in the other. The export of rod/hook-type proteins is followed by the export of the filament-type, and the switching of the substrate specificity occurs at a well-defined point in the assembly process to control the hook length, which is important for the proper hook function as a universal joint.

2.2.2 Growth of the Flagellar Filament

The flagellar filament is extended from the cell. Possible ways to construct such structures are either that constituent molecules are inserted at the base or they are transported to the distal end and bound there. As mentioned above, the latter is adopted by the bacterial flagellar filament assembly, probably because the bonding between the basal body, the hook, and the flagellar filament must always be tight and stable against the mechanical stress from high-speed rotation and quick reversal of

the motor with the long helical propeller in viscous environments.

Flagellin subunits passing through the central channel of the flagellum polymerize just below the cap one after another to form the long helical filament. The cap stays attached at the distal end during the filament growth, and the simplest role of the cap would be to prevent flagellin from leaking out. This results in an increase in the local concentration of flagellin at the filament end above the critical concentration for polymerization. However, the cap does not completely cover the openings because HAP proteins that are occasionally transported pass through the capped end. Just in case the filament is broken in the middle, those transported HAP2 molecules can bind to the broken end of the filament and form a new cap again. Thus, the cap appears to act as a gatekeeper, which can be recovered when it is lost. The cap may also induce a conformational change of flagellin for efficient polymerization because flagellin must be unfolded to fit in the narrow channel during its transport. For insertion of flagellin subunits, the cap must move up by steps to make a room for the next flagellin monomer. Thus, the cap must play apparently contradictory roles; it must remain stably attached while permitting the insertion of flagellin subunits.

Structure analysis of the cap–filament complex by electron cryomicroscopy showed that the pentagonal plate of the cap is attached to the distal end of the filament at five positions through the anchor domains of the cap, which look just like five legs, where these anchor domains show significant deviation from the fivefold symmetry (Fig. 9). The five anchor domains are well separated from one another, forming five gaps with different sizes and shapes between the plate and the filament end (Fig. 9). One of the gaps (Fig. 9c-1) is distinctly larger than the other four, having an inverted ''L'' shape and the size equivalent to domain D1 of flagellin. Because of the axial stagger in the lateral subunit packing, the end of the filament is not flat, but has five indentations around its circumference, where one of them is a double indentation. Thus, this is most likely to be the site of flagellin assembly.

Inside the filament just below the cap plate, there is a cavity ~30 Å wider than the central channel of the filament. Folded flagellin molecules cannot pass through the narrow central channel with a diameter of ~20 Å. Hence, flagellin definitely needs to be considerably unfolded until it reaches the distal end. This cavity may play some role in helping flagellin to fold up, perhaps in a similar way to Anfinsen's cage in chaperonin. The cavity appears to have the right size to accommodate only one flagellin subunit at a time, allowing its refolding without aggregation with other subunits.

During the growth of the filament, a large number of flagellin molecules, together with a small number of the hook-associated proteins, HAP1, HAP2, and HAP3, are synthesized in the cell and selectively translocated by the export apparatus into the long, narrow central channel of the flagellum, through which they are transported to the distal end by diffusion. This narrow channel would prevent unfolded flagellar proteins from undesirable aggregation.

The inner surface of the channel consists of mainly polar amino acids with one positively charged residue. The polar nature of the surface may be advantageous for fast diffusion of unfolded proteins, because unfolded proteins have many hydrophobic side chains exposed, which would be trapped on the channel surface of hydrophobic nature. This would also

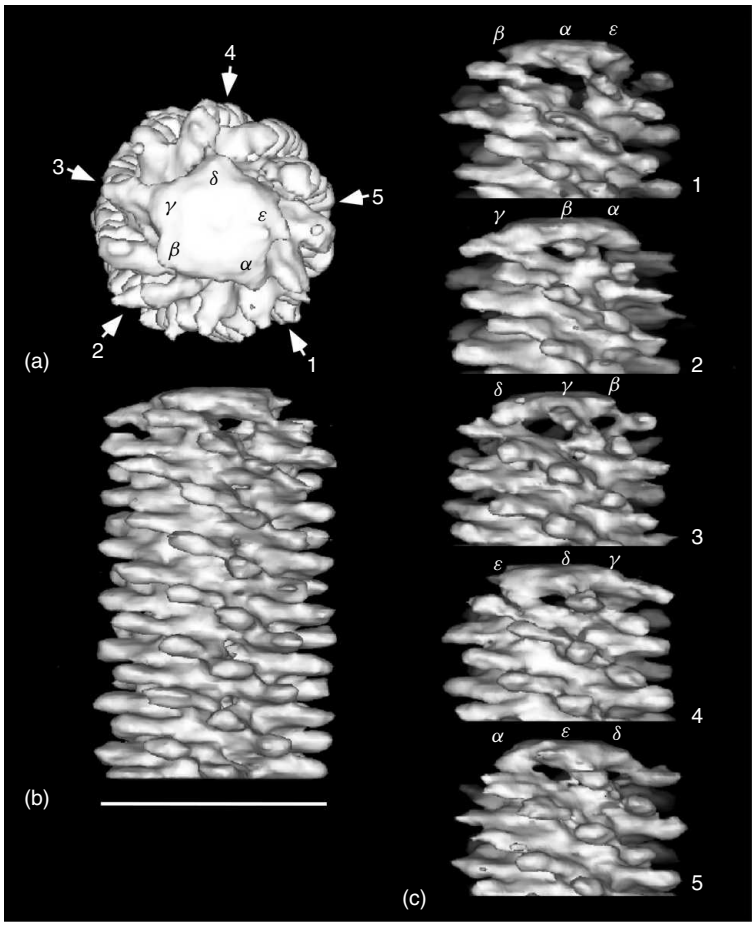

Fig. 9 Three-dimensional density map of the cap-filament complex and its central section. (a) End-on view from the top, showing a pentagonal shape of the plate domain of the cap. The five vertices of the pentagon are labeled with Greek letters, $\alpha-\varepsilon$, which are used to guide the orientation of the pentagon in the side views in (c). (b) Side view, showing a regular helical array of flagellin subunits and the plate domain of the cap. (c) Five side views, showing each of the five gaps between the plate and the filament end. The viewing directions are as indicated by arrows in (a), labeled with corresponding numbers. Greek letters labeling the vertices as in (a) also indicate the orientations of the pentagonal plate. Note that part of the gap in view one has a significantly larger axial extension than the other four gaps, and this is likely to be the site of assembly for the newly arriving flagellin subunit. Bar represents the diameter of the filament, 240 Å. Permission from Yonekura, K., Maki, S., Morgan, D.G., DeRosier, D.J., Vonderviszt, F., Imada, K., Namba, K. (2000) The bacterial flagellar cap as the rotary promoter of flagellin self-assembly, *Science* **290**, 2148–2152.

be a common feature of the type III protein export system including the needle complex of pathogenic bacteria.

Because of the symmetry mismatch between the helical subunit array of the filament with 11 protofilaments forming the tube and the pentameric annular structure of the cap, the five leg domains of the cap must have significantly different conformations from one another for interaction with flagellin. The flexible nature of the leg domain allows such polymorphic interactions, reducing conformational strains and permitting stable interactions between the two structures in spite of the symmetry mismatch. At the same time, the high conformational entropy of these cap anchor domains would counterbalance the strong binding of the cap to the filament as a whole for efficient insertion of flagellin.

Every insertion of a flagellin subunit is likely to force the cap to move into the next stable position energetically equivalent to the current position. A prediction from this structure and a previous discussion is that the cap moves up 4.7 Å and rotates 6.5° along the left-handed 5-start helix of the filament (Fig. 10). In terms of the cap conformation, the next position is approximately 65.5° away along the right-handed 1-start helix (arrangement of yellow subunits in Fig. 10). However, with permutation of the conformational states of the legs, which are 72° apart, a rotation of only 6.5° in the other direction would suffice. This would result in a roughly complete rotation of the cap by the assembly of 55 flagellin subunits. Upon every subunit incorporation, four legs of the cap rearrange their conformations and the last one changes its binding partner; namely, these legs walk along the helical steps of the filament end. These dynamic movements of the cap and its leg domains would be required for efficient promotion of the flagellin self-assembly.

The energy for the cap rotation with the conformational rearrangements is presumably supplied by the binding energy of newly incorporated flagellin subunit to domains of multiple subunits of flagellin and HAP2, where the binding occurs by concentration of flagellin within the channel. The energy to keep the effective concentration of flagellin at the distal end of the export channel above the critical concentration for its polymerization would therefore come from ATP hydrolysis by the type III protein export apparatus located at the cytoplasmic face of the flagellar basal body. The energy transduction network formed here is unique and interesting because the energy produced in the cytoplasmic space is transmitted quite a long distance (10 ~ 15 μm) through flagellin export to be used by the rotational movement of the cap at the end. The energy required for these movements would be relatively small because the process would involve a number of small conformational rearrangements in sequence, where the energy would propagate from one to the next.

2.3 Perspectives

The bacterial flagellum is a macromolecular complex made of ~25 different proteins and is used for bacterial swimming. Bacteria have evolved most of those various apparatuses for this specific purpose. Biochemical and genetic studies have identified functions of each protein and have played important roles in understanding the assembly process of the flagellum. Recent electron microscopy and X-ray crystallography have also been elucidating details of the components structures,

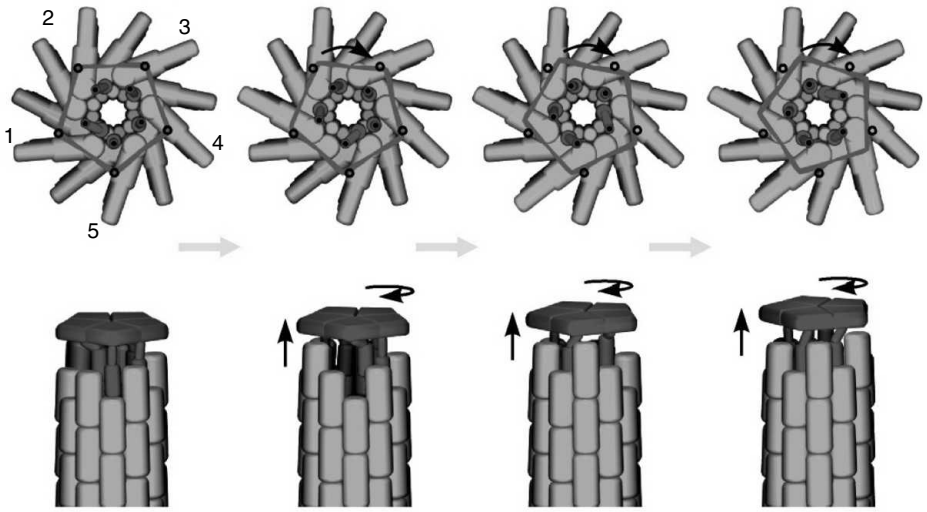

Fig. 10 Schematic diagram depicting the rotary cap mechanism promoting the flagellin assembly. This describes the rotation and axial translation of the cap plate and accompanied rearrangement of the legs upon every incorporation of a flagellin subunit (from left to right). Top view in the upper panel and an oblique view in the lower panel. In the upper panel, the cap plate is made transparent to show the different ways of leg domain binding, where black dots indicate the five positions of leg domain attachment to the plate. The plate and the black dots have strict fivefold symmetry, while the leg domains do not. In the lower panel, the outer domain of flagellin is removed for clarity. Subunits in yellow are newly incorporated flagellin molecules. Five open circles in the upper panel indicate the initial positions of the cap plate vertices as a reference for the cap rotation. The flagellin assembly proceeds along the 1-start helix, which is in the counterclockwise direction when viewed from the top, approximately at every 65.5° (360 × 2/11). This is also the angle of rotation after which the next binding site appears. However, because the legs of the cap are located every 72° (360/5), a 6.5° clockwise rotation with permutation of the leg conformations is sufficient to make the appropriate interactions between the leg and flagellin subunits. Numbers indicate the directions of views in Fig. 9(a). Animation at http://www.npn.jst.go.jp/yone.html. Permission from Yonekura, K., Maki, S., Morgan, D.G., DeRosier, D.J., Vonderviszt, F., Imada, K., Namba, K. (2000) The bacterial flagellar cap as the rotary promoter of flagellin self-assembly, *Science* **290**, 2148–2152. (See color plate. p. xxviii)

in particular, for the extracellular components. However, still little is known about molecular mechanisms of how each part of the flagellum functions. Obviously, we need high-resolution structures of not only the component proteins but also complexes made of many proteins. How the energy of ion flow is converted into the rotation of the flagellum would be the most important question to answer, and it still remains a mystery. High-resolution structure of the motor complex would be a starting point to solve the problem.

Keywords

Antibody Mimetic
A protein engineered to act as an antibody such that it binds target molecules other than its natural binding partners.

Affinity Reagent
An antibody, antibody mimetic or a peptide that has an affinity for a molecule of interest.

Bacteriophage/phage
A virus that infects bacteria.

Binder
Same as ''affinity reagent.''

CDR
Complementarity Determining Regions. Highly variable regions of the antibody light and heavy chain variable domains that are responsible for antigen recognition.

Fab
Fragment of antigen binding of antibodies generated by either recombinant methods or limited proteolysis.

scFv
Single-chain Fragment of variable region. A short fragment of an antibody molecule that is engineered in such a way that it contains only the variable regions of the light and heavy chains in a single polypeptide.

Molecular display refers to the presentation or the display of molecules – mostly proteins and peptides – on the surface of a virus, a cell, or a molecular complex such as a ribosome or messenger RNA. The coding information of the displayed molecule is carried by the entity displaying it, thereby establishing a physical link between the properties (phenotype) and DNA sequence (genotype) of the displayed molecule. All molecular display techniques have *in vivo* or *in vitro* methods for enrichment by selective propagation of the molecule with the desired properties. This, along with the genotype–phenotype link, allows large numbers (up to 10^{14}) of variations to be surveyed for the desired characteristics. These properties have made molecular display technologies a very valuable tool for the study of molecular interactions, the isolation of affinity reagents with increased affinities and stabilities, and the development of therapeutics with tissue- and cell-targeting capabilities. This article introduces different display methods, the types of random libraries most commonly used to isolate binders, and some of the interesting and creative applications of molecular display technologies in answering a variety of biological questions.

1 Display Methods

1.1 Phage display

In 1985, Dr George Smith, a professor at the University of Missouri-Columbia, published an article in which he described an experiment where he inserted a segment of the gene encoding the *Eco*RI restriction enzyme into the genome of the M13 bacteriophage. Smith found that fusions of the *Eco*RI protein fragment with one of the minor coat proteins were tolerated by the virus, as they still produced infectious particles. Interestingly, these particles incorporated the chimeric protein, and they could be fractionated from nonrecombinant virus particles with an antibody that recognized the expressed portion of the *Eco*RI protein. With sequential rounds of affinity selection, termed *biopanning*, the recombinant particles that displayed the antigen could be selectively enriched from an excess of nonrecombinant particles. These results led to the concept of ''phage display,'' in which coding regions for peptide or protein segments are inserted in a bacteriophage genome and the expressed peptide or protein segments are accessible for molecular interactions. The major benefit of phage display, as well as other display technologies we review here, is the physical linkage between the displayed entity (phenotype) and its genetic code (genotype), which permits a method for ''bar-coding'' and isolating rare peptides and proteins with desired properties from diverse libraries. In this section, we briefly discuss different molecular display methods that are in use today.

1.1.1 Bacteriophage M13

To date, bacteriophage M13 display has been the most extensively used display method. M13 phage particle are filamentous in shape (i.e. 9 nm wide, 900 nm long) and contain five types of coat proteins as well as a single-stranded DNA molecule (Fig. 1a). In the original experiments of

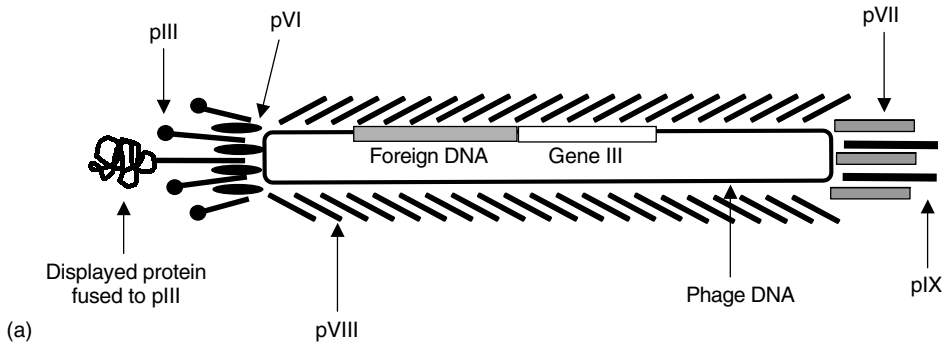

Fig. 1 Bacteriophage M13 display.
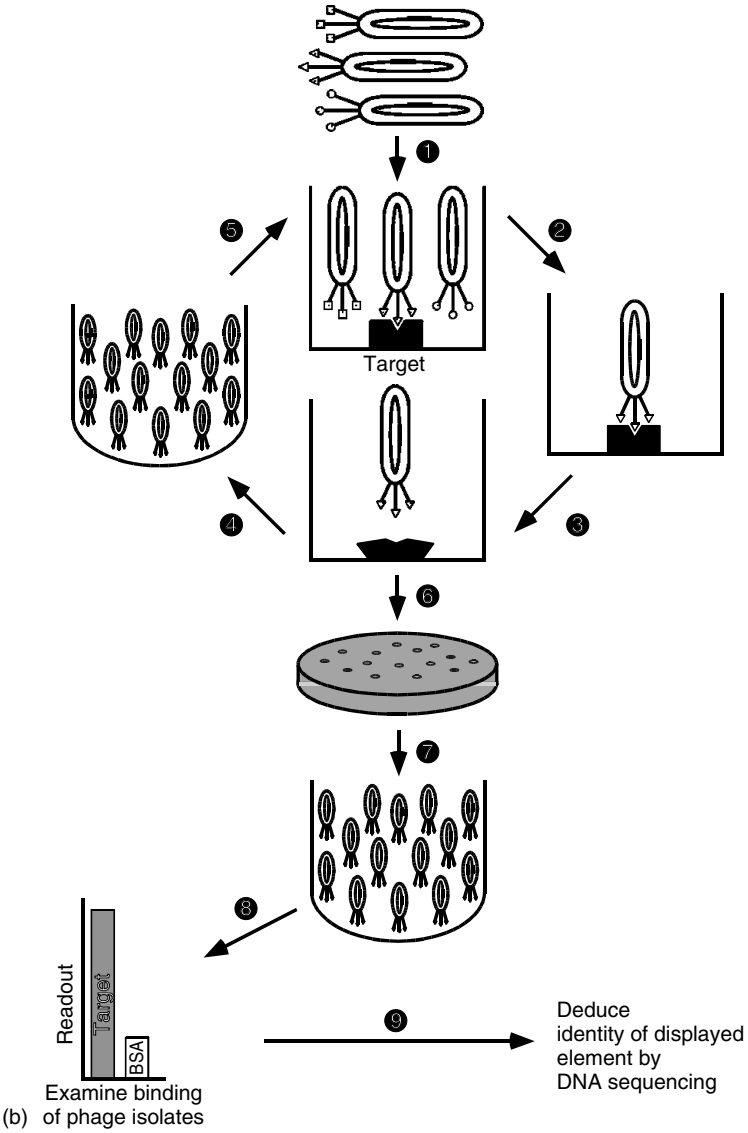
(a) Schematic representation of M13. (b) Affinity selection of phage-displayed libraries. The protein (pIII, pVI, pVII, pVIII, and pIX) and DNA (single-stranded) components of a prototypic bacteriophage M13 particle are shown. DNA fusions to the N-terminus of the coding region for mature protein III leads to the generation of a chimeric protein that is incorporated in the secreted viral particle. If the virus particle is assembled in an infected cell that carries a recombinant phagemid and a helper virus, display can be monovalent (shown); alternatively, use of a different vector can lead to pentavalent display (not shown). A population of virus particles displaying a library of antibody fragments, cDNA segments, combinatorial peptides, or engineered proteins can be fractionated by affinity selection. Phage are incubated in a microtiter plate well coated with a target protein and nonbinding particles are washed away, and retained particles are recovered by chemically denaturing the target. Infection of *E. coli* cells with the released particles amplifies the phage enriched for binding and the process is repeated two or more additional times. After limiting dilution of the final sample, individual clones are amplified and tested for binding to the target (and not a negative control protein) by an ELISA. DNA sequencing of the phage insert leads to identification of the affinity selected antibody fragment, cDNA segment, combinatorial peptide, or engineered protein.

Smith, protein fragments were displayed at the N-terminus of mature protein III. Fortuitously, the site chosen for display did not interfere with either virus morphogenesis or the infection process. Since then, research has shown that it is possible to display at the N-terminus of proteins III, VII, VIII, IX and at the C-terminus of proteins III, VI, and VIII. The display of proteins and peptides at the N-terminus of proteins III or VIII is most common.

Phage-displayed protein or peptide libraries are typically fractionated by affinity selection (Fig. 1b). A target protein is immobilized on a surface, incubated with an aliquot of viral particles, nonbinding particles are washed away, and bound particles are recovered. To release the bound particles without destroying their infectivity, it is possible to expose them to pH extremes (i.e. pH 2 or 12), protein denaturants (i.e. 6 M urea, 15 mM dithiothreitol), or proteases (i.e. trypsin, subtilase). Once the conditions for elution have been neutralized, the recovered phage can be used to infect *Escherichia coli* cells, thereby amplifying the selection output. Since bacteriophage M13 is not a lytic virus, infected cells secrete phage particles on a continual basis as they grow, yielding $\sim 10^{12}$ plaque-forming units (pfu) per milliliter in an overnight liquid culture.

The target proteins can be affixed to the surface of microtiter plate wells either directly by nonspecific adsorption or indirectly through a streptavidin-biotin



(b)

Fig. 1 (*Continued*)

linkage (i.e. the target protein is biotinylated and bound to immobilized streptavidin). Another option is to capture complexes formed between soluble biotinylated protein targets and phage on streptavidin-coated microtiter plate wells or magnetic beads. Finally, it is possible to select phages that bind to the surfaces of, or are internalized by, mammalian cells or tissues. In general, three rounds of affinity selection are sufficient to enrich binding phage particles from a library. After

confirming that the output phage clones actually bind to the target, often through an enzyme-linked immunosorbent assay (ELISA), sequencing the DNA insert of the individual phage clones reveals the coding sequence of the displayed peptide or protein.

Many of the proteins displayed on bacteriophage M13 adopt their native structure and activity, even though they are fused to a coat protein that is assembled into a viral particle. However, in some cases, the displayed protein interferes with the function of the coat protein, viral particle morphogenesis, or secretion of the viral particle by *E. coli*. In many of these situations, these limitations can be overcome by displaying the protein on a shortened version of the coat protein and providing the wild-type form of the protein, with the aid of a helper virus. Thus, instead of being displayed on all five copies of protein III (multivalent display), the protein can be displayed in a monovalent manner, with four copies of wild-type protein III available for attaching to the pili of *E. coli* cells and infecting them. M13 has been a versatile tool for the display of many different kinds of peptides and proteins, thereby leading to many interesting biomedical and biotechnical applications, as discussed below.

1.1.2 **Bacteriophage T7**

It has been possible to display proteins and peptides on a number of other bacteriophages as well. One popular virus is bacteriophage T7, in which it is possible to fuse peptides and proteins to the C-terminus of the 10B capsid protein. Vectors have been developed that direct display from 1 to 415 copies of polypeptides, 10 to 1000 amino acids in length, per virion. The low-valency display vectors are suitable for the selection of high-affinity ligands, while the higher valency display vectors enhance the recovery of low-affinity binders. Unlike the filamentous phage-display system, in which the displayed proteins need to be secreted into the periplasmic compartment of *E. coli* cells, T7 phage particles assemble in the cytoplasm, followed by lysis of the host cell. This characteristic overcomes the limited capacity of the protein secretion machinery of the *E. coli* cell and is more favorable for display of cytosolic proteins that carry reduced cysteine residues. The short life cycle (i.e. 2 h) for this lytic virus also makes it attractive for accelerating the screening process. Finally, since the protein of interest can be fused to the C-terminus of the major capsid protein, T7 phage is ideal for displaying segments of proteins encoded by cDNA fragments, which are typically biased toward containing C-terminal stop codons.

1.1.3 **Bacteriophage Lambda (λ)**

The λ display system has several attractive attributes. Compared to the T7 phage system, in which multivalent display of larger proteins has been reported to affect plaque formation, λ appears to tolerate display of proteins up to 300 amino acids in length on at least 90% of the copies of its capsid D protein. In addition, it is possible to display at either the N- or the C-termini of protein D. From a λ library displaying protein segments encoded by cDNA or genomic DNA fragments, one can identify interacting proteins for a variety of targets.

1.2 **Cell Surface Display**

In the recent years, cell surface display has emerged as an alternative to phage display. While cells can display thousands of copies of a peptide or protein, one of the biggest

advantages of cell display is that one can use fluorescence-activated cell sorting (FACS) to identify and quantitate positive clones during the selection process. In addition, the carbohydrates on the cell surface offer a largely inert surface in terms of nonspecific binding to target proteins, potentially leading to lower numbers of false positives. This section discusses various bacterial and yeast cell surface display techniques.

1.2.1 Bacterial Display

A variety of expression systems for the display of either short peptides or fully folded proteins on *E. coli* and, to a lesser extent, on gram-positive bacteria have been developed. Peptides or proteins have been targeted to the cell surface of bacteria by fusing them with protein components of the outer membrane, pilus, or flagella of *E. coli*. It has also been possible to display on the surface of gram-positive bacteria, *Staphylococcus carnosus* and *S. aureus*. Through FACS, bacteria that bind a particular fluorescent target protein can be enriched over 10 000-fold from a library, and with subsequent rounds of growth and cell sorting, they are eventually purified. Bacterial display has many applications, including vaccine development, mapping epitopes, bioremediation, biocatalysis, and biosensor development.

1.2.2 Yeast Display

Surface display of proteins on baker's yeast *Saccharomyces cerevisiae* was first reported in 1997 and, since then, it has been gaining increased use in the field of protein engineering. This system utilizes the cell surface receptor a-agglutinin, which mediates cell–cell adhesion during mating of the "a" and "α" haploid forms to produce a diploid yeast cell. The large subunit of a-agglutinin, Aga1p, is anchored to the yeast cell wall by a covalent β-glycan linkage, while the small subunit Aga2p is linked to Aga1p by two disulfide bonds (Fig. 2a). Proteins of interest can be displayed as C-terminal fusions to the Aga2p protein without disturbing assembly of the agglutinin protein heterodimer on the cell surface. To tightly regulate display, expression of the *Aga2p* gene fusion is directed by the GAL1-10 promoter, which is completely repressed by growth on glucose and induced by galactose. Thus, a yeast-display library can be propagated in the presence of glucose without expression of the fusion protein, which prevents loss of recombinant clones whose Aga2p fusion protein expression is toxic. A variety of proteins have been successfully displayed on yeast, including scFv's, single-chain T-cell receptors, Fabs, a single-chain form of the class II major histocompatibility complex product, and selectins.

Affinity selection of a yeast-display library is commonly performed by mixing the yeast cells displaying the protein of interest with a fluorescently labeled target, followed by sorting of the yeast-target complexes using FACS. The amount of Aga2p fusion protein displayed on cells can be monitored in parallel through detection of an epitope added to the C-terminus of the Aga2p fusion protein (Fig.2a). With FACS, the enrichment of yeast displaying an interacting protein is evident in real time during each selection step (Fig.2b). One less-expensive alternative to FACS is the use of streptavidin magnetic beads with biotinylated targets for fractionating yeast. To date, yeast display has been applied primarily to *in vitro* evolution studies in which 10^5 to 10^7 variants of a protein are generated and screened for an

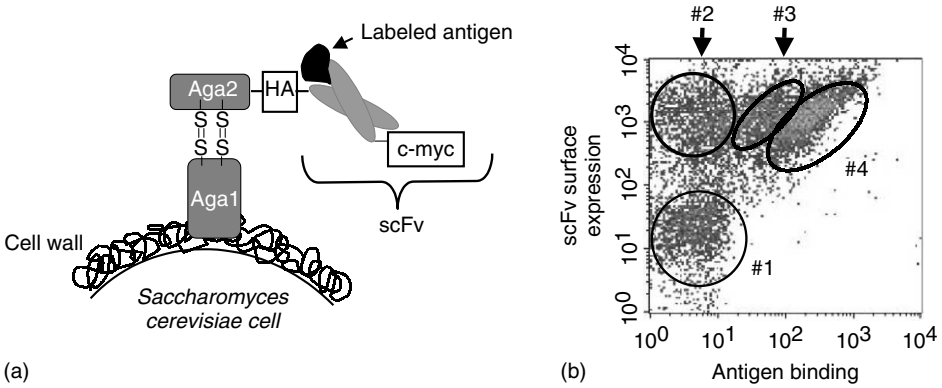


Fig. 2 The yeast display method. (a) Aga2-scFv fusion displayed on the surface of *S. cerevisiae*. The protein of interest (i.e. an scFv) is expressed on the yeast surface as a C-terminal fusion to Aga2. Aga2 is attached to Aga1 by disulfide bonds, which in turn is anchored in the yeast cell wall. An HA tag C-terminal to Aga2 and a c-myc tag C-terminal to the scFv allow determination of the fraction of cells expressing the recombinant clone and those expressing Aga2 only. The antigen is labeled so that the yeast, which bind the antigen, can be fractionated and quantified using FACS. (b) Bivariate flow cytometric analysis of yeast-displayed antibody fragments. A greatly enriched antigen-binding population shows the discrimination of clones with slight differences in affinities and nonbinding populations. Cells are double labeled with biotinylated antigen/streptavidin-phycoerythrin, and anti-c-myc/anti-mouse FITC labels. Subpopulation #4 expresses higher affinity scFv's and labels more brightly with antigen at a given scFv expression level. Subpopulation #3 expresses somewhat lower affinity scFv's, and subpopulation #2 does not detectably bind antigen. Subpopulation #1 is not expressing scFv on the cell surface. (Figure 2b was reproduced with permission from Feldhaus, M.J., Siegel, R.W. et al. (2003) Flow-cytometric isolation of human antibodies from a nonimmune *Saccharomyces cerevisiae* surface display library, *Nat. Biotechnol.* **13**(2), 163–170.)

optimal variant. Even though yeast cells are not efficiently transformed with exogenous DNA, such studies generally involve smaller libraries of variants, which are easily achievable using yeast. Recently, Feldhaus and coworkers reported the construction and characterization of the first nonimmune human scFv library displayed on yeast, with a diversity of 10^9 clones. By performing a considerable number of transformations, it was possible to overcome the low transformation efficiency of yeast. With this library, scFv's to many targets have been isolated and demonstrated to have affinities similar to those obtained from phage-display libraries. Moreover, the researchers were also able to amplify this library 10^{10} fold without loss of diversity, suggesting that the original library is essentially an unlimited source for scFv's.

1.3 In vitro Display

In vitro display technologies utilize cell-free systems, and are not limited by the biology of the virus or cells. *In vitro* libraries are typically 10^{12} to 10^{14}, orders of magnitude higher than the largest phage libraries available, which allows a much larger "sequence space" to be surveyed and tighter binders to be selected.

1.3.1 **Ribosome Display**

Ribosome display was first applied to the display of short peptides and later modified to display proteins and protein fragments. In this technique, a linear DNA segment, containing a promoter recognized by the T7 RNA polymerase, a ribosome binding site, the coding region for the peptide or protein, and a spacer region encoding a long unstructured stretch of amino acids, is transcribed and translated *in vitro* (Fig.3a). If the translation product lacks a stop codon, the nascent polypeptide chain remains tethered to the ribosome and

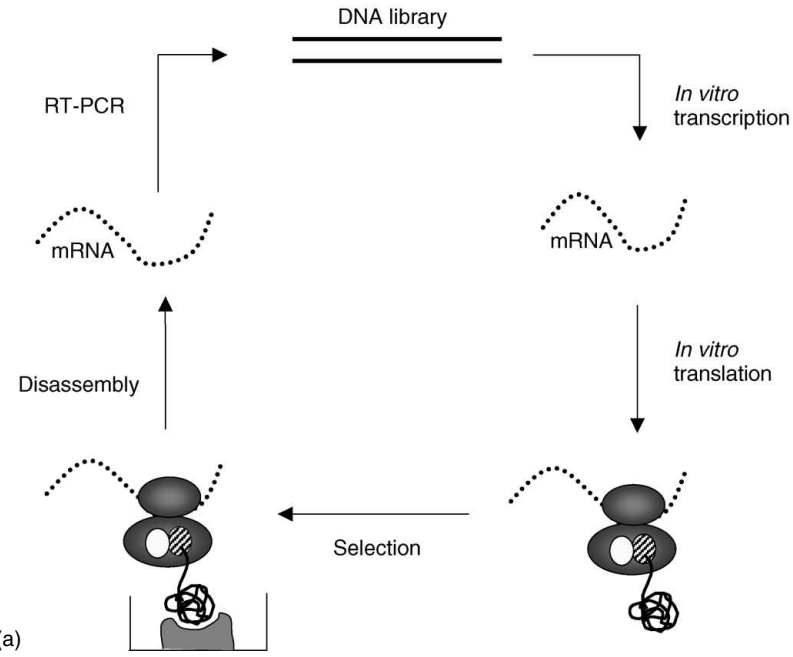

Fig. 3 Affinity selection using *in vitro* display techniques: DNA and mRNA are denoted by solid and broken lines, respectively. (a) Ribosome Display. A DNA library encoding proteins of interest is transcribed and translated *in vitro*. A long C-terminal spacer allows proteins to fold and lack of a stop codon prevents release of the protein. The mRNA-protein–ribosome complex is then used for selection on immobilized target. At the end of the selection step, the bound mRNA is released from the ribosome with EDTA, reverse transcribed, and the resulting cDNA is amplified by PCR and used either for another round of affinity selection or cloned and sequenced to determine its identity. (b) mRNA display. A DNA library encoding proteins of interest is transcribed *in vitro* and a short segment of DNA carrying a 5′ psoralen linker and a 3′ puromycin moiety (P) is hybridized to the mRNA. Photo-activation of the psoralen leads to covalent cross-linking of the mRNA and the DNA. This complex is then *in vitro* translated. The ribosomes stall at the RNA–DNA junction, allowing the puromycin to enter the A site of the ribosome (shaded circle) and accept the nascent polypeptide chain. Because of the covalent linkage of the mRNA and the protein, the ribosome can be dissociated at this point. Second-strand synthesis of the mRNA results in a DNA–RNA hybrid that is more stable and the selections are performed with this complex. At the end of the selection, the DNA is amplified by PCR and either used for additional rounds of selection or sequenced to yield the identity of the clone.

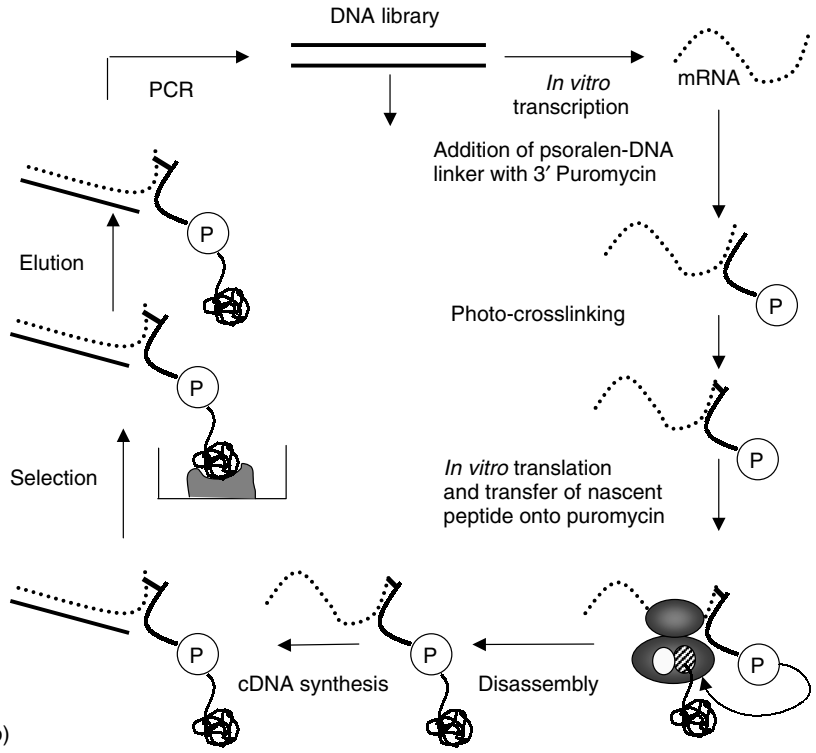

Fig. 3 (*Continued*)

mRNA, thereby creating a physical linkage between the genotype and phenotype. This RNA-protein complex, which is stabilized by high concentrations of magnesium and low temperatures, can be used in selection experiments. Sequences of interest are recovered by reverse transcribing the selected mRNA molecules, synthesizing the second DNA strand, and amplifying the resulting DNA by the polymerase chain reaction (PCR). Through additional rounds of *in vitro* transcription, translation and affinity selection, peptides or protein fragments with interesting properties are isolated from libraries.

Ribosome display has been mainly used for the display and selection of scFv's. By this technique, scFv's selected from libraries of $>10^{12}$ molecules generally have dissociation constants in the low nanomolar range. Since the PCR amplification step in the screening process can be modified to be mutagenic (i.e. 0.5–1%), this technique is well suited for molecular evolution experiments such as affinity maturation and stability engineering of scFv's. In one application, a low fidelity DNA polymerase was used for PCR amplification of scFv's selected with bovine insulin, and after six cycles of selection, scFv's were recovered with dissociation constants of 80 picomolar. In another study, scFv's that recognize the guanine quadruplex of human telomeric DNA sequences were isolated from a ribosome display library and demonstrated to have K_d values in the low nanomolar range. In immunofluorescence studies, it was possible to prove the existence of

the guanine quadruplex *in vivo,* for which there had previously been no conclusive evidence, using such antibody fragments.

Ribosome display has also been used to select for proteins with catalytic activity. A beta-lactamase could be enriched over an inactive mutant by ribosome display using a suicide substrate inhibitor. Even though the active enzyme made a covalent bond with the suicide substrate, chelating the magnesium ions releases its encoding mRNA for subsequent amplification and rescreening steps.

1.3.2 mRNA Display

mRNA display was first reported in 1997 by two groups working independently. This technique is similar to ribosome display, except that the nascent polypeptide chain is linked to its mRNA covalently by use of the aminoacyl-tRNA mimic puromycin. Puromycin can be attached to the 3′ end of the mRNA by hybridizing with single-stranded DNA containing psoralen and puromycin moieties, followed by photomediated cross-linking of the hybrid through the psoralen. This RNA–DNA partial duplex is then used for *in vitro* translation: the ribosome stalls at the RNA–DNA junction, which allows time for the puromycin to enter the ''A site'' of the ribosome and accept the nascent polypeptide chain, thereby creating a covalent linkage between the mRNA and the protein it encodes (Fig. 3b). To stabilize the mRNA component of the complex prior to selection experiments, it is reverse transcribed or replaced by double-stranded cDNA, which is covalently attached to the protein and the selection is performed with this complex. Since proteins are covalently linked to their coding sequence, affinity selection experiments can be performed under stringent conditions.

A variety of peptides and proteins have been displayed on mRNA and have been used to isolate high-affinity reagents that bind RNA, small molecules, and other proteins. RNA-binding peptides, which bound their target with low nanomolar affinity and high specificity, were isolated from combinatorial peptide libraries of 10^{12} to 10^{14} individual members. Some of these peptides were even able to differentiate between a single nucleotide change in the loop structure of the RNA. From a combinatorial peptide library containing 80 randomized amino acids, specific binders of ATP have been isolated with high affinity ($K_d = 100$ nM). From tissue-specific cDNA libraries, interaction partners for the antiapoptotic protein Bcl-X_L, which included known partners as well as previously unidentified proteins, have been isolated. Finally, using this technology, it was possible to isolate antibody mimetics, which were based on randomizing residues within the tenth fibronectin type III domain, to tumor necrosis factor-α (TNF-α) with K_d values in the picomolar range.

mRNA display also lends itself to unique applications such as incorporation of unnatural amino acids and chemical adducts into the synthesized protein. Attachment of a penicillin moiety to a fixed cysteine in a combinatorial peptide library allowed identification of novel inhibitors of the penicillin binding protein 2a, which were 100-fold more potent than penicillin alone in inhibiting synthesis of bacterial cell walls. The same research group also introduced a biotinylated amino acid into a displayed peptide by adding a biocytin-charged amber suppressor tRNA to the *in vitro* translation reaction. The ability to use unnatural amino acids overcomes the diversity limits imposed by the 20 natural amino acids and

can lead to the identification of peptides and proteins with unique characteristics.

2 Types of Libraries

Molecular display technologies allow the recovery and identification of molecules with desired properties without the need for any prior sequence information. This property has made it possible to survey very large libraries(i.e. 10^9–10^{14} unique sequences) for those rare members with the desirable biochemical traits. In this section, we briefly discuss the different kinds of libraries that are often used to accomplish this previously daunting task.

2.1 Combinatorial Peptide Libraries

One of the most common uses for bacteriophage M13 has been the display of combinatorial peptides. Oligonucleotides, which are fixed in length but degenerate in sequence, are inserted into one of the genes encoding one of the six capsid proteins, thereby generating a library of combinatorial peptides displayed on the surface of phage particles. While there are many codon schemes to choose from, the degenerate regions are commonly based on the NNK coding scheme: N is an equimolar mixture of A, C, G, and T, and K is an equimolar mixture of G and T nucleotides. In this scheme, 32 codons encode one stop codon (TAG), which is suppressed in certain *E. coli* strains, and all 20 amino acids, which are represented once (C, D, E, F, H, I, K, M, N, Q, W, Y), twice (A, G, P, V, T), or three times (L, R, S). These combinatorial peptide libraries, also called *random peptide libraries*, typically contain over one billion clones, with each viral particle displaying a different peptide sequence fused to protein III. A variety of combinatorial peptide libraries have been constructed over the years, of 6 to 42 amino acids in length, and with no or several fixed amino acids, such as cysteines. (Since the phage particles are secreted into an oxidizing environment, peptides with even numbers of cysteines will form intramolecular disulfide bonds, thereby conformationally constraining the peptides.) While such libraries are diverse enough to encode all possible six and shorter amino-acid-long peptide sequences, there is evidence for exclusion from phage-displayed combinatorial peptide libraries of certain peptide sequences that interfere with viral morphogenesis or secretion through the membrane.

2.2 scFv and Fab Libraries and Fab Libraries

Fabs or scFv's have been successfully displayed on the surface of bacteriophage. Creation of large repertoires of antibody fragments from antibody genes, as well as the development of high-throughput screening methods, reduce, and in some cases eliminate, the need to use animals for antibody production. Phage-displayed antibodies have been generated from a variety of animals (camel, chimpanzee, human, llama, mouse, and rabbit), and since each phage particle displays a single antibody fragment, they are monoclonal in nature. M13 phage display remains the most extensively used method for isolation of antibody fragments partly because it is well suited for the expression of immunoglobulin protein fragments; as the chimeric antibody-capsid proteins pass through the periplasm during viral morphogenesis, the disulfide bonds in the heavy

and light chains have an opportunity to form properly.

There are three routes for generating antibody display libraries. First, it is possible to immunize an animal with an immunogen, recover the circulating B-cells, extract mRNA, and clone portions of the immunoglobulin heavy and light chains into a display vector. In this manner, monoclonal antibodies can be rescued from immunized animals *in lieu* of generating hybridomas. It is possible to use this method to obtain neutralizing antibodies from human patients that recovered from exposure to infectious agents, such as the human immunodeficiency virus, respiratory syncytial virus, and herpes simplex virus, and *Helicobacter pylori*. Second, it is possible to generate a naïve antibody library by amplifying the variable regions of the heavy and light chains from a small number of B-cell donors and then cloning and displaying a large number of pair-wise combinations. From libraries containing over one billion clones, it is possible to generate antibodies to most antigens with nanomolar dissociation constants. Third, it has been possible to randomize the codons for the hypervariable regions within the heavy and light chain variable regions, thereby generating ''semisynthetic'' antibody libraries. All three approaches have been extremely productive in generating antibodies for basic research, biotechnology, and medical applications.

In the postgenomic era, antibody fragments can help to define novel gene function and to measure protein expression in pathological states. In addition to these new directions, antibody fragments have begun to show success in clinical diagnosis and as immunotherapies for cancer and other diseases. Radiolabeled antibodies, derived by display technologies, have great potential for cancer imaging and treatment. Antibodies have also been exploited for prodrug therapy, cancer treatment, and gene delivery by fusing them with different molecules such as toxins, enzymes, and viruses. The list of FDA approved antibody therapeutics against cancer, viral infection, and inflammatory disease is growing rapidly (http://www.fda.gov/cber/efoi/approve.htm).

2.3 Antibody Mimetic Libraries

Although scFv's and Fabs have been used extensively as affinity reagents, they sometimes suffer from poor yields when expressed in *E. coli* and can be unstable. These drawbacks have prompted a search for alternative scaffolds, which bind targets with comparable specificity and affinity. These mimetics generally have improved stabilities, better expression yields in *E. coli*, and, in some cases, are smaller, inherently fluorescent, or lack disulfide bonds. Mimetics without disulfide bonds can be used for *in vivo* inhibition of cytoplasmic targets because they adopt stable structures in the reducing environment of the cytoplasm. Although it remains to be determined if antibody mimetics can replace therapeutic antibodies, they offer great promise in research and diagnostics.

Antibody mimetic libraries can be constructed by randomizing residues that are exposed on the scaffold surface or by grafting the complementarity determining regions (CDR) of antibodies onto the scaffold. Some of these mimetics have been termed *affibodies, monobodies*, and *anticalins*, which are based on a three-helix bundle Protein A domain from *Staphylococcus aureus*, the tenth type III domain of human fibronectin, and

lipocalin, respectively. Affibodies, monobodies, and fluorobodies have been used to generate binders with nanomolar to picomolar affinities against protein targets, whereas anticalins have been mainly used for isolating binders with midnanomolar affinity for small molecules such as fluorescein and digoxigenin. Monobodies isolated against estrogen receptor complexed with different ligands have been employed as intracellular detectors for ligand-induced conformational changes of the target. Recently, repeat proteins such as ankyrins and leucine repeats have been explored as antibody mimetics where multiple randomized repeats are stacked together to create a binding surface for targets. The modular structure of this class of antibody mimetics may allow greater flexibility in designing binders with greater diversity and increased surface area for interactions with their targets. Ankyrins are also promising reagents for intracellular protein ''knock-out'' experiments because they do not require disulfide bond formation for their stability.

2.4 cDNA and Genomic DNA Libraries

Bacteriophages have also been used to display libraries of protein segments encoded by complementary DNA (cDNA) fragments. Libraries of plant, fungal, and dust mite cDNAs have been cloned and displayed on bacteriophage M13 for the purpose of identifying human allergens: the libraries are screened with serum IgE and phage-displaying reactive allergens are selected and subsequently identified by DNA sequencing. Bacteriophage λ and T7 have been shown effective in displaying protein fragments encoded by cDNA segments cloned at the C-terminus of their major capsid proteins. Libraries of cDNA inserts corresponding to mRNA purified from different cell types are now widely available and such libraries have been screened extensively for interacting with specific protein, RNA, DNA promoter, carbohydrate, or small chemical molecules.

3 Applications

3.1 Protein Function and Target Validation

3.1.1 Mapping Protein–protein Interactions with Peptides

Peptide ligands selected from a phage-displayed library appear to bind preferentially to ''hot spots'' on the surface of protein targets. A hot spot is defined as a small region on the surface of a protein, often composed of several hydrophobic, disordered amino acids, which binds other proteins or small molecules. Peptide ligands selected from a phage library tend to home in on hot spots and to mimic proteins that normally interact with the target protein. In fact, very often, the primary structures of the selected peptides resemble regions within the interacting proteins. This phenomenon has been termed an example of *convergent evolution*, where the biological and molecular evolution has yielded similar results. Consequently, phage display has proven very useful in mapping the protein–protein interactions of extracellular and intracellular proteins (Fig. 4). Several notable examples include defining the epitopes of monoclonal and polyclonal antibodies, discovering agonists and antagonists of hormone receptors, and defining the specificity of protein interaction modules

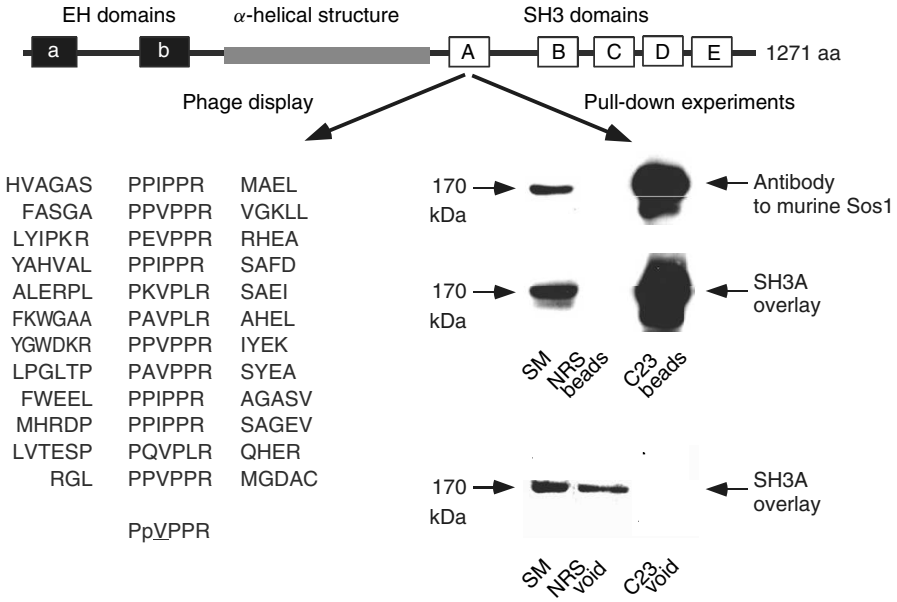

Fig. 4 Mapping protein–protein interactions. The intersectin protein consists of two Eps15 Homology (EH) domains, a central coiled-coil region, and five Src Homology 3 (SH3) domains. A protein fusion between the N-terminal SH3 domain (SH3A) and the glutathione-S-transferase (GST) can be used to affinity select phage-displayed combinatorial peptide libraries. The predicted amino acid sequences of selected phage are aligned to reveal the motif, PpVPPR, where p is commonly proline. Computer searches with the motif matched a sequence (PPVPPR) within the Son-of-Sevenless (Sos) protein, suggesting that it may interact with intersectin. Sos was demonstrated to interact with intersectin through pull-down and coimmunoprecipitation experiments. Sos is 170 kilodaltons (kDa) and reacts with C23, a commercial monoclonal antibody. SM and NRS void refer to starting material (rat brain extract) and nonreactive serum respectively.

present in signal transduction and endocytic proteins.

3.1.2 Elucidation of Enzyme Function

Peptides selected for binding to enzymes appear to preferentially bind at the active sites of the enzymes, even though they are not involved in protein–protein interactions. In a survey of ten different enzymes, peptide ligands were isolated for eight of the target proteins, and at least six were shown to inhibit the enzymes. Synthetic forms of the selected peptides acted as competitive inhibitors in activity assays. In addition, they were used in displacement assays to screen libraries of chemicals and natural products for those that prevented binding of the peptide ligands to the enzymes *in vitro*, and thus bind to the active site of the enzyme. Such peptides can also be expressed inside cells where they can bind to the enzyme and inhibit its *in vivo* activity; in some cases, inhibition leads to a cellular phenotype.

It is also possible to screen combinatorial peptide libraries to define the substrate specificity of enzymes. By tethering phage through an anchor sequence, the

substrate specificity of proteases can be defined: only those viruses that carry a cleavage site in the linker composed of combinatorial peptides are released. In this manner, ''substrate phages'' have been identified for a variety of proteases, such as subtilisin, factor Xa, furin, matrix metalloproteinases, urokinase, granzyme B, prostate-specific antigen, and HIV-1 protease. Substrate phages have also proven useful for defining the substrate specificity of various protein tyrosine kinases.

3.1.3 Functional Knock-outs Using Intrabodies

Over the past few years, several groups have expressed antibody fragments inside cells. These intracellularly expressed antibody fragments, also named ''intrabodies,'' can provide a way of validating targets by blocking pathways in cells. While only a small fraction of phage-displayed scFv molecules can fold properly in the reducing environment of the cytoplasm, those which do fold are still able to bind to their targets and yield interesting biological results, such as arresting HIV infection, blocking apoptosis, disturbing proper embryo development, and arresting oncogenic transformation of cells in culture. Future experiments in functional genomics will rely heavily on antibodies or mimetics that fold efficiently inside cells.

3.2 Drug Discovery and Therapeutics

3.2.1 Identification of Tissue- and Tumor-specific Markers via Whole-cell and *in vivo* Panning

Phage-displayed peptide and scFv libraries have also been used successfully for affinity selections against target mixtures present on the surface of cultured mammalian cells or tissues. Because whole-cell or tissue panning bypasses the need to purify the antigen, this method is useful for generating affinity reagents against antigens that are hard to purify, such as transmembrane proteins. Using this procedure, scFv's and peptides have been isolated for cell surface receptors such as urokinase plasminogen activated receptor, thrombin receptor, melanocortin receptor, and cell types such as colorectal tumor cells, lymphatic vessels, and *Bacillus* spores. Cell- and tumor-specific peptide ligands and antibodies have great potential usefulness in profiling the type or the stage of cancer in a manner similar to expression profiling using DNA microarrays.

In working with intact cells, scientists have realized that phage particles that promote cellular internalization can be selected from a display library. After incubating the phage particles with intact cells, the unbound phage are washed away and the cells are lysed in order to recover the internalized phage. Internalizing scFv's, which were shown to recognize the ErbB2 antigen, have been identified for SKBR3 breast cancer cells, and when fused to liposomes, target delivery into ErbB2 expressing tumor cells. Peptides selective for internalization by fibroblast cells, laryngeal carcinoma cells and ECV304 endothelial cells, and the human urothelium have been reported.

Phage-displayed combinatorial peptide libraries have also been used in *in vivo* panning. In a series of ground-breaking papers, Renata Pasqualini and Erki Ruoslahti injected phage particles displaying combinatorial peptides into mice, dissected out various tissues, amplified the bound phage

particles in *E. coli*, and repeated the selection process several times. Individual clones, when tested, were confirmed to bind selectively to their respective tissue targets. Similar experiments have also been conducted in humans: phage particles have been injected into patients and peptides were identified that bind selectively to human vasculature. Such ''organ homing'' peptides can be linked to drugs, and adenovirus or adeno-associated virus, for the purpose of targeting the delivery of the drugs or gene therapy agents respectively.

3.2.2 Screening of Small Molecule Inhibitors Using Surrogate Peptide Ligands

Since peptide ligands selected from a phage-displayed combinatorial peptide library often bind at sites of protein–protein interactions or catalysis, assays for discovering small molecule inhibitors can be developed. For example, peptides chemically synthesized with fluorophores attached at one end can be incubated in microtiter plate wells with the target protein and compounds from natural and chemical libraries. If the compound does not bind to the target, the fluorescence polarization of the labeled peptide will become anisotropic because of binding of a small peptide to a larger target molecule. On the other hand, if the compound binds to the target, thereby blocking peptide binding, the fluorescence polarization of the peptide will be isotropic, because it is free in solution. High-end devices can scan 96-, 384-, 1536-, or 6144-well microtiter plates rapidly in a laboratory, thereby permitting research groups to survey libraries of thousands and thousands of compounds for potential inhibitors. This general approach has lead to the discovery of compounds with potential antimicrobial activity.

3.2.3 Zinc Fingers for Controlling Gene Expression

One fruitful avenue for designing affinity reagents has been with zinc fingers, which typically bind DNA. Multiple zinc fingers can be displayed on phage and can bind to specific DNA sequences, with each finger (30 amino acids) roughly binding three adjacent bases in a double-stranded DNA molecule. Thus, it has been possible to randomize residues within a phage-displayed zinc finger and select for variants that could bind to specific double-stranded DNA molecules. Through a concerted effort, zinc fingers that bind to many different DNA triplet sequences have been identified. Such fingers can be ''stitched'' together to make polydactyl fingers (i.e. 6 adjacent zinc fingers) that recognize unique 18-bp sequences with subnanomolar to femtomolar dissociation constants. One practical consequence of this work is that it is now possible to introduce engineered finger proteins into cells and induce or repress expression of specific genes. It will be interesting to follow how this approach matures.

3.3 Protein Engineering and Industrial Applications

3.3.1 Molecular Evolution

Molecular evolution refers to improvement of the desired characteristics of a molecule using techniques such as error-prone PCR or DNA shuffling and the appropriate selection protocols. This strategy is used extensively in protein engineering in situations where the mutations that might bring about a desired property cannot be predicted from existing biochemical or structural information, necessitating the generation and screening of random mutants. With the application of different display technologies, the number

of clones that can be screened at the end of a molecular evolution experiment has increased by orders of magnitude. This allows researchers to access larger numbers of permutations for the desired protein products. By enhancing the specificity, affinity, or stability of an scFv, one can generate a reagent with improved therapeutic value. Using yeast display and a combination of DNA shuffling and error-prone mutagenesis, the dissociation constant of an scFv that binds fluorescein was improved over three orders of magnitude to 48 femtomolar.

Through phage display and targeted mutagenesis, the dissociation constant of an anti-Vascular Endothelial Growth Factor (VEGF) antibody fragment was improved 120 fold over the parent molecule. Finally, by using ribosome display, an antihemagglutinin scFv was evolved to have increased stability in DTT. Some of the clones were able to bind their antigen when expressed in the reducing environment of the *E. coli* cytoplasm. These types of antibody fragments would be invaluable as reagents for protein ''knock-out'' and target validation studies.

Phage-displayed proteins are amenable to selection for their resistance to extreme conditions, such as denaturants, detergents, proteases, and elevated temperatures. Thus, one can select for protein variants that maintain their shape or function under such conditions. For example, from a phage library displaying mutated ribonuclease T1 molecules, it was possible to select variants more stable than the wild-type molecule. A screen of mutagenized *Bacillus subtilis* cold shock protein CspB led to the identification of variants that had higher thermal or chemical stability, depending on whether the selection was done at elevated temperature or in the presence of a denaturant, respectively. In another case, from a library of mutagenized alpha-amylase proteins, variants were discovered that hydrolyze starch at low pH conditions that favor industrial applications. Finally, a partially unfolded four-helix bundle protein, apocytochrome b(562), was phage displayed and challenged with a protease, to yield a stably folded form of the protein.

3.3.2 Bacterial and Yeast Surface Display as Biocatalysts

Ability to display proteins and enzymes on bacterial and yeast cell surfaces have proven to be valuable in industrial applications. For example, construction of a whole-cell biocatalyst with its sequential reaction has been achieved by the genetic immobilization of two amylolytic enzymes on the yeast cell surface. Organophosphorus hydrolase, a bacterial enzyme that has been shown to degrade a wide range of neurotoxic organophosphate nerve agents, was evolved and displayed on *E. coli* surface to hydrolyze methyl parathion, providing the possibility of creating biocatalysts that can degrade pesticides (i.e. diazinon and chlorpyrifos) and nerve agents (i.e. sarin and soman). *E. coli* and *Moraxella sp* (a bacterium known to survive in contaminated environments) have been successfully explored to display phytochelatins, which could be used for bioaccumulation of cadmium and mercury, providing a new method for treating heavy metal contamination. Finally, display of glycosyltransferases at the yeast cell surface through a cell wall anchored protein has shown potential as a simple *in vitro* method for oligosaccharide synthesis using the yeast intact cell as a biocatalyst.

3.3.3 Nanotechnology

Recently, several groups have screened phage-displayed combinatorial peptide

libraries for peptides that bind to inert surfaces. Even though such peptide-surface interactions are intrinsically weak, they are detected because of the avidity resulting from the pentavalent presentation of protein III on M13. Peptides have been discovered that bind selectively to polystyrene, semiconductor surfaces, silver nanoparticles, and ZnS or CdS nanocrystals. These peptides have great promise for engineering new nanostructures.

4 Outlook and Perspectives

Scientists in both basic science and biotechnology have used display technologies creatively. While the technologies have matured over the past few years, new applications appear on a regular basis, suggesting that they will continue to impact various fields of science in a significant manner for the next 10 years. In particular, it is anticipated that these technologies will contribute significantly in the emerging areas of nanotechnology and personalized medicine, where display technologies can be used for fabricating nanostructures and treating disease respectively.

Keywords

Cytokines
Constitutively released or produced upon cell activation, cytokines are soluble mediators – sometimes membrane bound – binding to receptors on target cells and inducing, modulating, or inhibiting cellular functions. Most cytokines are produced by immune cells and act on immune cells, but cytokines are produced by numerous cell types and act on a great variety of cells, accordingly displaying a large spectrum of activities. They are characterized by their redundancy, their synergistic action, and their regulatory loops. Those produced constitutively contribute to the tissue and systemic homeostasis. The cytokine are elements of a universal language used by cells to communicate.

Chemokines
A subfamily of cytokines with structural similarities and sharing the property to recruit cells within the extravascular space of the tissues (chemotaxis), either at homeostasis or during inflammatory processes.

Interferons (IFN)
A subfamily of cytokines sharing an antiviral bioactivity. Interferons are characterized by different subgroups (type I and II), depending on their origin. In addition to their common property, some (e.g. IFNγ) are involved at different stages of the onset and further development of the immune responses, or play a role during gestation in mammals (e.g. IFNτ).

Interleukin (IL-)
A convenient name to classify cytokines. The numbers have been given as a reflection of their discovery through the years. This term does not define a family, since none are biochemically or biologically related. However, the most recent interleukins have been described after gene banks and are thus related to previous well-known interleukins. When the word was created (1979), there was only IL-1 and IL-2.

Receptors
The receptors of cytokines allow the cells to respond to the signal delivered by cytokines. They can involve 1, 2, or 3 different chains. Most chains are constituted with one extracellular domain, one transmembrane domain and one intracellular domain, except the chemokine receptors that are constituted by 7 transmembrane domains.

Cytokines are proteins or glycoproteins produced by cells and acting on other cells that display on their surface the specific cytokine receptor. Cytokines are words used by the cells to communicate. Alone or within a determined sequence, these mediators lead the responding cells to modify its function (e.g. secretion, proliferation, induction, inhibition, enhanced/reduced function, migration, apoptosis, etc.). Despite cytokines having been mainly discovered by immunologists as a product of cells of the leukocyte lineages, they are now recognized as elements of a universal language used by most cells of any other lineages. Accordingly, they are essential for many events through the life (reproductive tissue remodeling, embryogenesis, steady state and adaptive hematopoiesis, surveillance and maintenance of the tissue structure, functions by the immune system, cell survival, and cell death, etc). They also allow a dialogue with the central nervous system and some cytokines may modify different behaviors (fever, anorexia, sleep, etc). They usually act within their vicinity, but they can also act via an endocrine fashion. Their productions are tightly controlled within a complex network of positive and negative loops. They are a prerequisite to control infection by invasive microorganisms, but their exacerbated production can be deleterious at the local or systemic levels. Their half angel–half devil aspect has rendered them difficult to use with therapeutic purposes, although some recombinant cytokines or some cytokine-neutralizing strategies have been successfully used in different pathological conditions.

1 Historical Record

The history of cytokines can be divided in four main steps through the years. The first step corresponds to the identification of biological activities of factors present in cell culture supernatants or within the blood stream (late 40s–early 70s). During the second step (late 70s–early 80s), the purification and the biochemical characterization of these factors allowed to reach the stage of defined molecular entities. During the third step (mid-80s–mid-90s), the cloning of the coding and noncoding sequences, the production of recombinant cytokines, as well as the production of genetically manipulated mice extended the understanding of the complexity of the cytokine-mediated language. Since the late 90s (the fourth step), the discovery of new cytokines has been relying on the availability of different genome sequences and the different gene banks. In the later case, bioactivities of newly identified cytokines remained to be discovered. Probably, the first reported bioactivity was the induction of fever and the discovery of an endogenous pyrogen in the late 40s, early 50s. The purification of human endogenous pyrogen was published in 1977 by Charles Dinarello. This allowed the identification of endogenous pyrogen as interleukin-1 (IL-1). It definitively established that fever was due to endogenous factor(s) and not directly induced by microbial products. After the cloning of IL-1 in 1984, this was confirmed the following year, when injection of recombinant IL-1 was shown to induce fever in rabbits. Later, genes encoding different IL-1 homologues have been identified by means of their significant sequence similarities to IL-1, but further studies are required to know whether some members of the IL-1 family (IL-1F5–10) are pyrogenic. The other earlier-described bioactivity was reported in 1957 by Isaacs and Lindenmann. They showed that resistance to virus development could be conferred to a cell by another virus-infected cell. This bioactivity interfering with virus spreading was named ''interferon.'' In the 60s, numerous bioactivities had been detected in supernatants of lymphocytes. Accordingly, identified as nonantibody mediators, D. Dumonde et al. proposed in 1969, the word ''lymphokines.'' In the following years, the word ''monokine'' was employed to characterize other bioactivities found in monocyte/macrophage supernatants. In the 70s, the most famous lymphokine was the ''macrophage migration inhibitory factor'' (MIF). Owing its name to its *in vitro* property, MIF had been first identified in 1966 as a T-lymphocyte-derived product associated with delayed-type hypersensitivity. In the absence of cell lines producing high amounts of MIF, its biochemical characterization was delayed. The cloning of this molecule occurred in 1989, long after its discovery. In the meantime, MIF-like activity was reported in cultures of fibroblasts, and S. Cohen et al. found a MIF-like activity in the supernatants of virus-loaded cell lines. Then, it appeared evident that lymphokines were incorrectly named because many cell types other than lymphocytes could produce similar bioactivities. And, in 1974, S. Cohen coined the name ''cytokine.'' Indeed, MIF is a good example of a cytokine produced by many cell types, including macrophages, dendritic leukocytes, endothelial cells, epithelial cells, and fibroblasts. Most fascinating was the rediscovery of MIF as a product of the pituitary gland, further reinforcing the concept of cytokine and illustrating that, sometimes,

the border between cytokines and hormones may be difficult to draw.

Names of factors were traditionally reflecting their various biologic activities identified in different laboratories. This approach resulted in an imprecise and redundant nomenclature. In 1979, during the 2nd international Lymphokine Workshop in Ermatingen (Switzerland), it was decided that the name ''interleukin'' (IL-) be given to two different characterized factors. Under the new term IL-1 were gathered numerous names or acronyms defined according to one of the properties of this cytokine: osteoclast activating factor (OAF), lymphocyte activating factor (LAF), B-cell activating factor (BAF), epidermal thymocyte activating factor (ETAF), T-cell replacing factor III (TRFIII), leukocyte endogenous mediator, endogenous pyrogen, mitogenic protein, catabolin, hemopoietin-1, and so on. The name interleukin (between leukocytes) was obviously not the best choice since these factors were not restricted to leukocytes, but it had been mainly chosen by immunologists too self-absorbed, who were considering the immune system working independently of the other systems. When interviewed about it, Stanley Cohen specified: ''It is a common misconception that the term interleukin was accepted for adoption by the nomenclature committee. When it was proposed, both Byron Waksman and I, as Co-chairs, felt it would turn out to be too restrictive (even then) and there was general agreement by the committee that it would be premature to refer to mediators as interleukins. This view was conveyed to the proposers. However, shortly thereafter, an editorial appeared in Journal of Immunology stating that the term 'interleukin' had been discussed and considered by the committee (true) and that henceforth the term would be used in scientific communications by the scientists writing the editorial. This was a true-true-unrelated kind of position to take, but it caught on in the general scientific community.''

The last neologism, ''chemokine,'' was created in 1992 to gather under one name a large family of small biochemically related cytokines, all possessing chemoattractant properties.

The availability of the first cloned molecules allowed major progresses, not only in fundamental research but also for clinical applications. While growth hormone was the first recombinant molecule used in humans in 1980, interferon-alpha was the first cytokine injected in humans in 1981, and IL-2 the second in 1985. Indeed, in 1984, 10 000 L of supernatants of activated Jurkat cell were required to prepare 30 mg of natural IL-2; the following year, 10 L of supernatants of recombinant *Escherichia coli* expressing the *IL-2* gene were sufficient to prepare 1 g of recombinant IL-2.

2
A Universal Language of Cells

2.1
Definitions

Cytokines have been defined by immunologists as cooperative factors produced by activated lymphocytes, dendritic leukocytes, macrophages that induce, modulate, favor, increase, inhibit cell proliferation, cell differentiation, or cell activities such as antibody production. The onset of the messages delivered by these soluble (or membrane-bound) molecules relies on the binding to their specific receptors displayed on the surface of the immune cells, a process leading to an intracellular

signaling cascade. However, far from being limited to the leukocyte lineages, this is a universal language of cells of the whole body, independently of their lineages, their nature, and their localization. This is probably the main difference between cytokines and other soluble molecules such as neuromediators mainly produced by the brain and the neurons, or hormones mainly produced by the endocrine system (Table 1).

Like hormones, cytokines can act in an endocrine fashion, but their actions mainly occur within the cellular microenvironment in a paracrine fashion. However, since some cytokines can be expressed on the cell surface of the producer cell, cytokines can act in a juxtacrine fashion within a close contact between cells. Finally, cytokines can act as an autocrine factor for a cell that both produces a cytokine and displays its receptor (Fig. 1).

Cell interactions involve more than one cytokine. One can consider each cytokine as a word, and the full sentence that will finally emerge is the reflection of the delivery of different cytokine-mediated signals. Together, these signalings lead to orientate the activities of the target cell. Thus, the order of delivery of cytokines has major consequences on the nature of the message. Furthermore, the concentration of cytokines, their localization, the nature of the target cell, and the timing are important parameters that affect the exact nature of the cytokine-initiated process.

Tab. 1 Comparison between hormones and cytokines.

	Sources	***Targets***	***Activities***	***Action***
Hormones	Secreted by a unique cell lineage	Specificity rather limited to one single type of target cell	Single action	Endocrine
Cytokines	Produced by many cell types	Numerous target cells	Wide spectrum of activities (redundancy)	Paracrine Juxtacrine Autocrine Endocrine

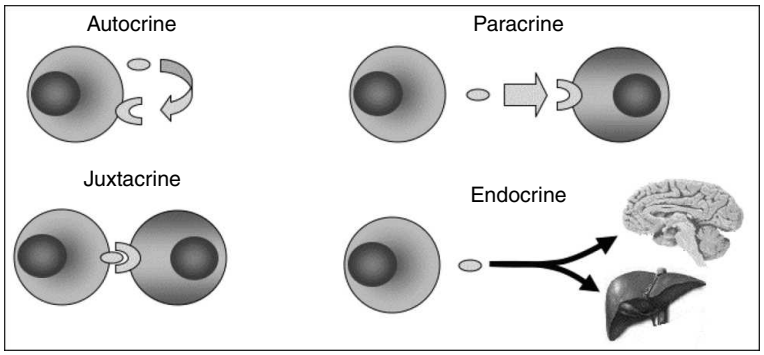

Fig. 1 Mode of action of cytokines.

In most cases, constitutive production of cytokines is limited and most cytokines are produced upon activation of cells. However, highly sensitive readout assays have allowed to determine a constitutive production at homeostasis in numerous tissues and cells.

2.2 Families

The classification of cytokines can be achieved according to (1) a common bioactivity: antiviral activity (interferons), chemoattraction (chemokines), hematopoiesis (colony-stimulating factors, CSF); (2) a common biochemical structure, suggesting a common ancestral molecule (chemokines, tumor necrosis factor (TNF) family); or (3) the sharing of a common chain of a receptor (gp130 cytokine family) (Table 2). Different subfamilies of interferons are known. Twenty-six genes of IFNα have been identified, of which at least five are pseudo genes. Interferons-alpha are produced by leukocytes and interferon-beta is produced by fibroblasts. IFNγ produced during immune response is a potent macrophage activator. IFNω is induced by virus, IFNτ is produced by trophoblast, and IFNκ is expressed by keratinocytes. Among chemokines, four different subfamilies can be identified on the basis of the highly conserved presence of the first two cysteine residues, which are either separated or are not separated by other amino acids: the CCL, CXCL, CX3CL, and the CL

Tab. 2 Families of cytokines.

Interferons	IFNα, IFNβ, IFNγ, IFNδ, IFNκ, IFNτ, IFNλ
Interleukins[1]	IL-1α, IL-1β, IL-1Ra, IL-18, IL-1F5-10 | IL-2, IL-15, IL-21
	IL-10, IL-19, IL-20, IL-22, IL-26 | IL-12, IL-23, IL-27
	IL-17A-E, IL-25 | IL-28, IL-29 | IL-3, IL-4, IL-5, IL-6, IL-7
	IL-8 (CXCL8), IL-9, IL-11, IL-13, IL-14, IL-16
Hematopoietic factors	M-CSF, G-CSF, GM-CSF, Stem cell factor
Chemokines	CCL1 . . . CCL28 ; CXCL1 . . . CXCL16 ; XCL1, XCL2 ; CX3CL1
TNF superfamily	TNF, Ltα, Ltβ, NGF, CD27L, CD30L, CD40L, CD137L, APRIL, BAFF, FasL, GITRL, LIGHT, OPGL TRAIL, RANKL, TWEAK, VEGI.
Growth factors	TGF$\beta_{1,2,3}$
Gp130 cytokine family	IL-6, IL-11, CNTF, LIF, Oncostatin-M, Cardiotrophin-1

[1] Biochemically related interleukins are framed.
APRIL: apoptosis-inducing ligand; BAFF: B cell-activating factor; CCL: chemokine CC ligand; CNTF: ciliary neurotrophic factor; CSF: colony-stimulating factor; CXCL: chemokine CXC ligand; GITRL: glucocorticoid-induced TNF receptor family related gene ligand; IL-1F: IL-1 family; LIF: leukemia inhibitory factor; LIGHT : lymphotoxins, inducible expression, competes with HSVglycoprotein D for HVEM, a receptor expressed on T-lymphocyte; Lt: lymphotoxin; OPGL: osteoprotegerin ligand; RANKL: receptor activator of NF-kappaB ligand; TGFβ : transforming growth factor-β; TRAIL: TNF-related apoptosis-inducing ligand; TWEAK: TNF-like weak inducer of apoptosis; VEGI: vascular endothelial cell growth inhibitor.

chemokines. The assigned numbers of interleukins only reflect the timing of their discovery. Thus, some interleukins are also hematopoietic factors (e.g. IL-3 previously named multi-CSF), chemokines (IL-8, also named CXCL8), or even interferon (IL-28 and IL-29 are identical to IFNλ). The first interleukins have been discovered as bioactive factors, and there are no similarities in their amino acid sequences. However, there are some homologies in tertiary and quaternary structures and similar helical structures are found. The more recently discovered interleukins have been identified in gene banks according to sequence homology to previously identified interleukins. The TNF ligand superfamily gathers 18 distinct members that include soluble molecules with biochemical homology as well as membrane-bound ones. There are few other cytokines that can be displayed at the plasma membrane of the producing cells: IL-1α, IL-10, IL-15, and IFNγ. The TNF ligand superfamily also includes a growth factor (i.e. nerve growth factor). Usually, growth factors have a rather narrow spectrum of activity, are produced constitutively, are not acting on hematopoietic cells, and thus are distinct from cytokines. One exception is the transforming growth factor-β family (TGFβ), particularly because at least one member, namely TGFβ1, displays anti-inflammatory properties.

Localization of genes on chromosomes is known, and often genes of a family are gathered on the same chromosome (e.g. IL-1α, IL-1β, IL-1 receptor antagonist on human chromosome 2; most CXCL chemokines on human chromosome 4; most CCL chemokines on human chromosome 17). Most cytokines are glycosylated, their molecular weight ranging between 7 and 30 kDa. Most cytokines are monomers (e.g. IL-1, IL-2, IL-3, IL-4. . .), and few are homodimers (e.g. IL-8) or homotrimers (e.g. TNF). Some are heterodimers like IL-12, IL-23, and IL-27: IL-12 and IL-23 sharing the same p40 chain. Some are heterotrimers like lymphotoxin-β (Ltβ) that is the association of Ltα and Ltβ chains.

3 Receptors

3.1 Families

Most cytokine receptors had been characterized once their ligands had been identified, but there were few receptors, called *orphan receptors*, that were known before their ligands (e.g. c-kit, the receptor of stem cell factor; CD40, the receptor of CD40L; IL-1 receptor-related protein-1, part of the IL-18 receptor, etc). In most cases, receptors are the association of more than one transmembrane chain. Usually, one chain is essential for the binding (α-chain), while the second chain is required to initiate the intracellular signaling (β- or γ-chain). Some chains are common for receptors of few cytokines; this is the case of the gp130 chain of the receptors of IL-6, IL-11, CNTF, LIF, Oncostatin-M, and Cardiotrophin-1, or the gamma chain of IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Cytokine receptors are characterized by domains derived from ancestral common genes. In terms of evolution, it would be interesting to decipher which mutations in genes coding for cytokines or for cytokine receptors were first fixed. A common domain, called *hemopoietin receptor superfamily domain* characterized by the presence of four cysteine residues and a conserved sequence tryptophan-serine-x-tryptophan-serine, defines a family of numerous cytokine receptors (Fig. 2).

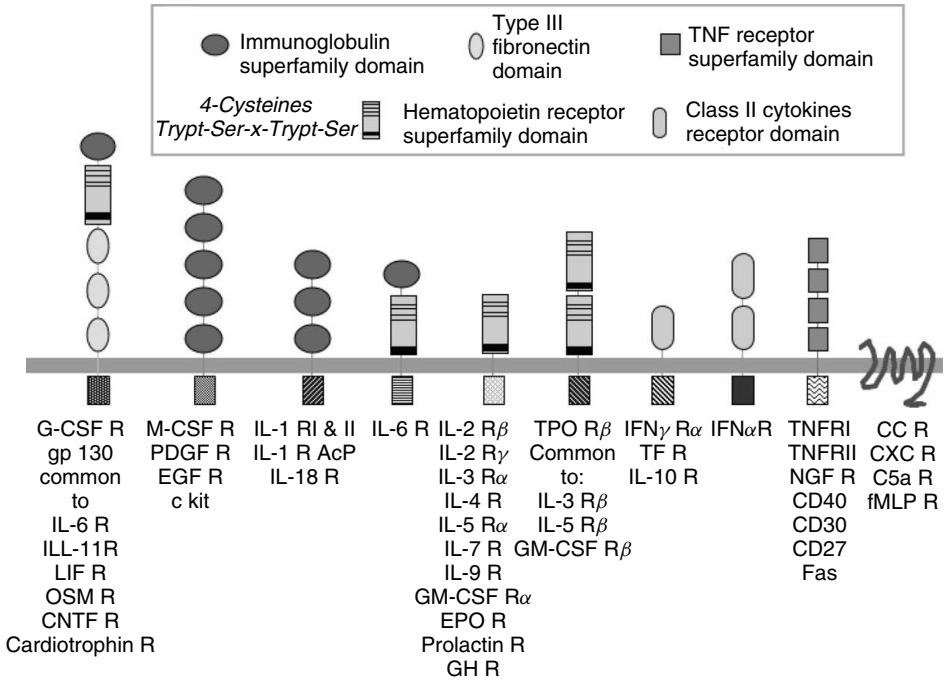

Fig. 2 Families of cytokine receptors.

Most interestingly, this family of receptors also includes receptors for hormones (e.g. growth hormone, prolactin) or the hematopoietic factor (e.g. erythropoietin). This domain can be duplicated (the common β chain of IL-3R, IL-5R, and GM-CSFR) or be associated with other domains like an immunoglobulin-like domain (IL-6Rα) or a fibronectin type III–like domain (gp130, G-CSFR). Another important family is the TNF receptor family. The activation by TNF is consecutive to the bridging of similar chains of the TNF receptor by the cytokine. Each cytokine receptor is highly specific for its ligand, except the TNFR p55 and p75 that bind both TNF and Ltα, and the chemokine receptors that can bind various chemokines. Chemokine receptors, constituted by a 7-transmembrane chain, are similar to receptors for other chemoattractant molecules such as the anaphylatoxin C5a or the bacterial fMet-Leu-Phe peptide. Cytokine receptors are often internalized after ligation to their ligands, and their expression can be induced, down- or upregulated.

3.2 Signaling

Upon binding of the cytokine to the extracellular domain of receptors, the intracellular receptor domains become associated with a variety of signaling molecules. A cascade of phosphorylation of various adaptor proteins occurs following interaction of the intracellular domain of the receptors with cytoplasmic tyrosine kinases (e.g. Janus kinases, Jak). Phosphorylation of latent cytoplasmic transcriptional activators (e.g.

signal transducers and activators of transcription, STAT) allows their dimerization and their translocation into the nucleus where they bind to specific sequences present in promoters of certain genes. Other pathways involving the mitogen-activated protein kinase (MAPK) and other kinases lead to the activation of various transcription factors (e.g. c-fos/c-jun, NF-κB, etc). Some signaling pathways are shared with other receptors. This is the case of the IL-1 and IL-18 receptors of which the intracellular domain is similar to the toll-like receptors (Toll–IL-1 Receptor, TIR domain). Thus, similar adaptors (e.g. MyD88, IRAK, etc) are involved after interaction of the respective receptors with their ligands, either members of the IL-1 family or pathogen-associated molecular patterns (PAMPs) such as endotoxin (lipopolysaccharide). Intracellular domain of some receptors (TNFR p55; Fas; TRAIL R) possesses a death domain that initiates a specific signaling cascade, leading to apoptosis.

3.3 Soluble Receptors

Receptors are integral part of the cytokine network (*cf* Sect. 7): not only can their membrane expression be modulated but they also exist as soluble molecules. Indeed, most cytokine receptors, except the chemokine receptors, can be shed from the cell surface after enzymatic cleavage following or not following a neosynthesis. As shown in Fig. 3, depending upon the nature of the receptor, its soluble form can behave as an inhibitor (e.g. soluble IL-1R, soluble TNFR) and can prevent the cytokine from reaching the membrane form. It can also be a carrier, protecting the cytokine within a complex, and increasing

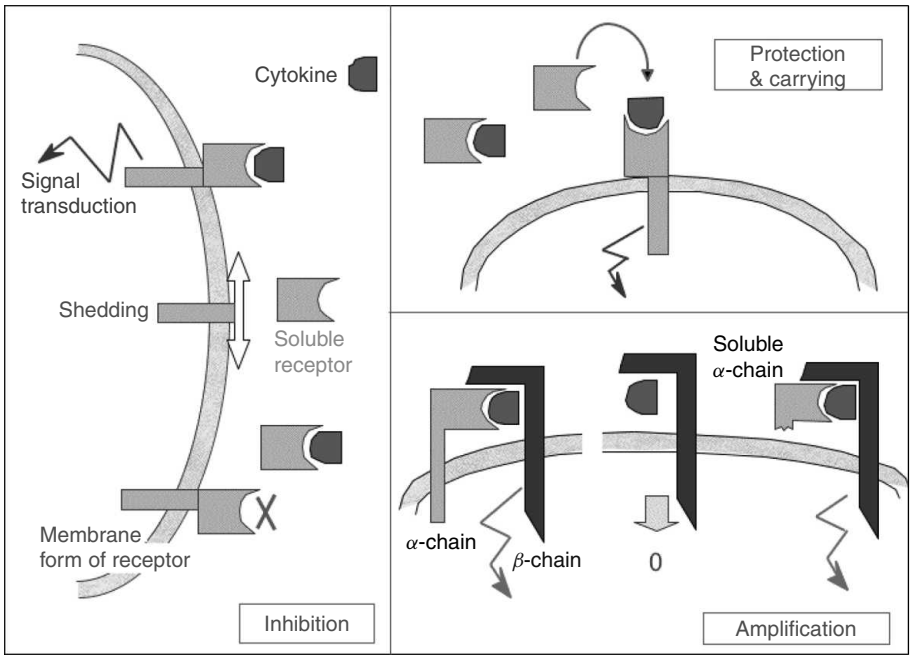

Fig. 3 Different properties of soluble receptors.

its half-life in the plasma or other biological fluids. Then, the dissociation of the cytokine-soluble receptor complex can allow the release of the cytokine close to a membrane receptor (e.g. TNFR). Lastly, in the case of a receptor constituted by one α-chain that binds the cytokine and one β-chain that recognizes the bound cytokine, the soluble α-chain receptor can enhance the responsiveness to the cytokine or can even allow the responsiveness of cells missing the α-chain, but expressing the β-chain. One example of the latter case is provided by the soluble IL-6R that, together with IL-6, controls the switch of leukocyte recruitment during inflammation.

4 Functions

4.1 Hematopoiesis

Production of leukocytes within the bone marrow is a very active and efficient process (4×10^8 white cells/leukocytes per hour in humans). Numerous cytokines, expressed at homeostasis in human bone marrow contribute to hematopoiesis, while others (like GM-CSF) are only active during infection to further increase the renewal of available leukocytes. Maturation, proliferation, and differentiation of bone marrow progenitor cells are under the control of different cytokines acting concomitantly. For example, IL-1 alone is unable to allow the differentiation of bone marrow precursors cells, but it acts in synergy with other hematopoietic cytokines. IL-3 and stem cell factor (also named *c-kit ligand*) are cytokines with a wide spectrum of activity, acting on pluripotent hematopoietic stem cells. GM-CSF favors the differentiation of myeloid progenitors cells, while M-CSF or G-CSF are specific of monocyte/macrophage and granulocyte lineages respectively. IL-6, IL-11, and mainly thrombopoietin favor thrombocytopoiesis, leading to megakaryocyte development and platelet production. Interleukin-5 has been identified as a major regulator of eosinophil development and function. Interleukin-7 is the main cytokine of lymphopoiesis required for the development of B, alpha-beta, and gamma-delta T-lymphocytes. Most of these hematopoietic cytokines also act as activators of mature cells and as antiapoptotic ligands.

4.2 Immune Response

4.2.1 Innate Immunity

Innate immunity is characterized by a response localized within the site of infection (Fig. 4). Epithelial cells and leukocytes residing in the extravascular space of the tissue (mast cells, resident macrophages, and immature dendritic leukocytes), and endothelial cells of the microvessels are triggered by microorganisms and microbial-derived products and release inflammatory cytokines (e.g. IL-1, TNF, IL-12, IL-18, etc). These cytokines further activate the endothelial cells of the postcapillary venules, leading to the increased adherence of circulating leukocytes and to coagulation process. Other cytokines, such as IFNγ, are produced within an amplificatory loop. Local production of chemokines contributes to the recruitment of new leukocytes from the blood compartment to further prevent the infectious process. Cytokines contribute to enhance the antimicrobial activities of newly recruited neutrophils and monocytes/macrophages (e.g. production of free radicals, enhanced phagocytosis), and the

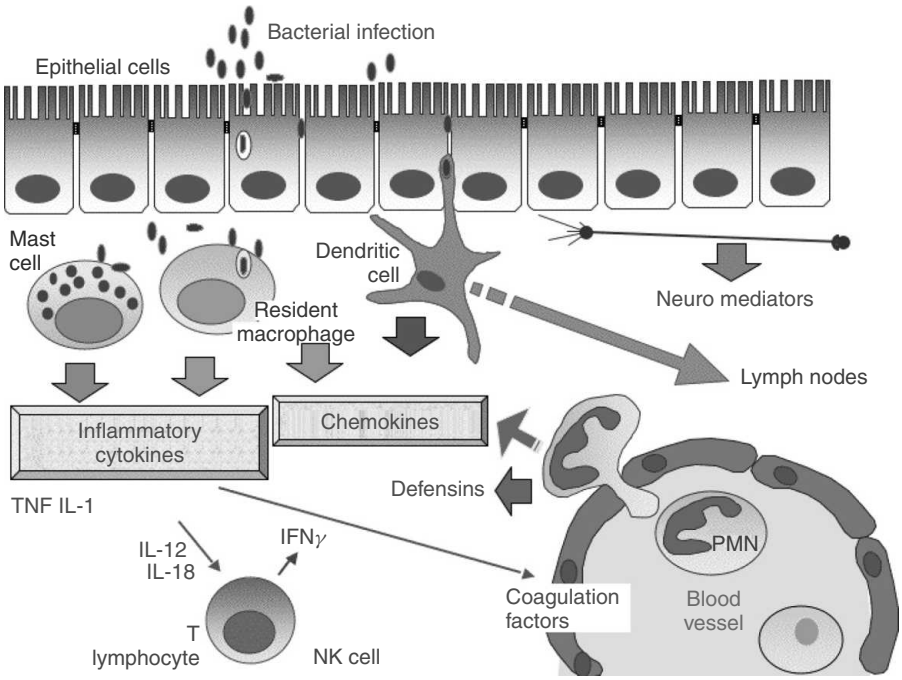

Fig. 4 Cytokines and soluble mediators as coordinators of regulated processes taking place in a bacteria-loaded sites.

antiviral activity of natural killer (NK) cells. Human leukocytes release defensins, a kind of natural antibiotics that contribute to limit bacterial dissemination. Neuromediators help control the inflammatory process. In addition to local responsiveness, a systemic response occurs, which includes fever, a reflection of the presence of pyrogenic cytokines within the plasma (e.g. IL-1, TNF, IL-6). Hyperthermia contributes to the anti-infectious process by enhancing some immune cell activities, and by reducing bacterial growth or viral replication. Finally, the production of hematopoietic cytokines (e.g. GM-CSF) further increases the number of leukocytes otherwise known to contribute to the clearance of the microorganisms and to the initiation of the healing process.

4.2.2 Adaptive Immunity

Adaptive immunity is characterized by processes relying on unique properties of the secondary lymphoid organs. Briefly, in secondary lymphoid organs such as the peripheral lymph nodes, professional antigen-presenting cells (dendritic leukocytes and mononuclear phagocytes), after processing of the native antigen, display on their membranes antigenic peptides and interact with T-lymphocytes, expressing a T-cell receptor able to specifically recognize these peptides. B-lymphocytes recognize native antigen. As a result of the cross talks between antigen-presenting cells, T- and B-lymphocytes, T-lymphocytes proliferate and differentiate as primed effector or memory T-cells, and B-lymphocytes proliferate and differentiate as antibody-secreting plasma

cells. All these events are controlled by cytokines. For example, within the secondary lymphoid organs, IL-2 and IL-4 favor T-cell proliferation, IL-12 activates cytotoxic T-cells, IL-2 and IL-4 allow B-cell proliferation, IL-4, IL-5, IL-6, IL-13, and TGFβ influence plasma cell differentiation and favor different immunoglobulin classes synthesis. Within microorganisms-loaded tissues, the effector T-lymphocytes, once reactivated could release IFNγ and GM-CSF that activate professional phagocytes conferring them microbicidal functions.

4.2.3 Th1 and Th2 Cytokines

In 1986, Tim Mosmann et al. described two types of murine helper $CD4^+$ T-cell (Th) clones defined according to the profile of released cytokines. Th1 cells produce IL-2, IFNγ, and Ltα, and Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13. Both subpopulations produce IL-3 and GM-CSF. Their differentiation from a Th0 precursor occurs, depending upon the cytokine environment (Fig. 5). Th1 and Th2 cells control each other: IFNγ derived from Th1 neutralizes Th2 cells, and IL-4 and IL-10 inhibit Th1 cells. Th1 cells are involved in cellular immunity and activate macrophages, Th2 cells are involved in humoral immunity and activate B-lymphocytes. Once stably differentiated as long-lived clones, some chemokine receptors allow to distinguish between these subpopulations: CXCR3 is mainly expressed on Th0 and Th1 cells, while CCR3 and CCR4 are expressed on Th2 cells. The Th1/Th2 dichotomy also exists in humans, as nicely illustrated by the early detection of Th2 cytokine mRNA expressed in response to an intradermal allergen challenge (immediate hypersensitivity) and the delayed detection of Th1 cytokine mRNA after tuberculin injection (delayed-type hypersensitivity). However, in most clinical settings, this dichotomy is not that obvious and mixed patterns are observed. More recently, other T-cell subsets with immunosuppressive properties have been characterized. Th3-type cells are a unique T-cell subset that primarily secretes TGFβ, provides help for IgA switch, and has suppressive properties for Th1 and other immune cell. Type-1 regulatory T-cells (Tr1) inhibit Th1 and Th2-type immune responses through the secretion of IL-10. They are also able to secrete TGFβ.

4.3 Cell Survival and Cell Death

Not only can cytokines be maturation and differentiation factors but they can

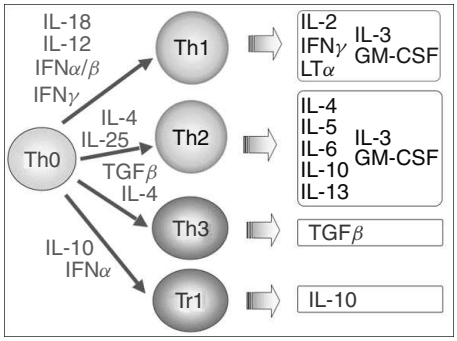

Fig. 5 T-cell subpopulations and the nature of environmental cytokines required for their differentiation.

also contribute to cell survival. For example, IL-2, IL-4, IL-6, IL-7, and IL-15 have all been shown to inhibit resting T-cell death *in vitro*. B-cell survival factors include IL-4 and B cell-activating factor (BAFF) of the TNF family. Plasma cell longevity depends on combination of IL-5, IL-6, stromal cell-derived factor-1α (SDF-1/CXCL12), and TNFα. IL-15 can sustain NK cell survival in the absence of serum. Indeed, *in vitro* serum starvation often leads to apoptosis that can be prevented by cytokines like TGFβ (e.g. survival of epithelial cell). Indeed, these properties reflect an antiapoptotic mechanism initiated by cytokines like the suppression of caspase activity or the maintenance or induction of Bcl-2 protein expression. RANKL suppresses apoptosis of primary cultured endothelial cells; SDF-1/CXCL12 enhances the survival of myeloid progenitor cells *in vitro*; stem cell factor (SCF) regulates the survival of cellular lineages by suppressing apoptosis. In addition to SCF, most hematopoietic factors allow survival of hematopoietic progenitors. In addition to sustain cell survival, cytokines can allow cell growth. For example, this is the case of IL-2 for T-cells, or IL-8 and some other chemokines that favor angiogenesis. Cytokines can also be growth factors for tumor cells; this is, for example, the case of IL-6 for malignant myeloma plasma cells. In contrast, certain cytokines can induce apoptosis of a variety of tumor cells and normal cells. Indeed, TNF was first identified in 1984 as a cytokine with antitumor effects, and other members of the TNF superfamily can induce proliferation, survival, as well as cell death: specifically, TNFα, FasL, TRAIL, and VEGI. The intracytoplasmic portion of their receptors contains a ''death domain.'' Upon activation by their ligands, the death domain recruits intracytoplasmic adaptors expressing a death domain: TRAF (TNF receptor-associated factor) and FADD (Fas-associated death domain), which in turn recruit the proform of caspase-8. Autoactivation of caspase-8 leads to the subsequent activation of caspase-3, a proapoptotic enzyme.

4.4 Link with the Central and Peripheral Nervous System

A cross talk exists between immune leukocytes and the central nervous system. Proinflammatory cytokines, particularly IL-1 and TNF, induce fever, anorexia, and slow wave sleep. Part of their activities is conveyed by the vagal nerve. Fever involves local production of IL-6 and prostaglandins E2 (PGE2). Certain chemokines are also pyrogenic (e.g. IL-8, MIP-1α, MIP-1β, RANTES), but do not induce PGE2. IL-1 and TNF also induce a neuroendocrine loop in response to their signal, hypothalamus produces a corticotropin-releasing factor (CRF), and CRF induces the release of adrenocorticotropin hormone (ACTH) by pituitary gland. ACTH induces the release of glucocorticoid by adrenals. Glucocorticoids inhibit the production of most cytokines and antagonize many of their activities. Vagal nerve releases acetylcholine that represses inflammatory cytokine production. In addition, other neural and neuronal mediators, adrenaline, vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP) are inhibitors of IL-1 and TNF production, while noradrenaline and substance P are potentiators.

4.5 Reproduction

There is compelling evidence that cytokines are involved in spermatogenesis, ovogenesis, and gestation. Cytokines play

an important regulatory role in the development and normal function of the testis. They are produced by Leydig cells, Sertoli cells, and germinal cells. Proinflammatory cytokines, including IL-1 and IL-6, have direct effects on spermatogenic cell differentiation and testicular steroidogenesis. Stem cell factor and leukemia inhibitory factor, cytokines normally involved in haematopoiesis, also play a role in spermatogenesis. Anti-inflammatory cytokines of the TGFβ family are involved in testicular development. TNFα, a secretory product of round spermatids, increases endogenous androgen receptors expression in primary cultures of Sertoli cells. Given the requirement of testosterone for spermatogenesis and the importance of androgen receptors in mediating Sertoli cell responsiveness to testosterone, the stimulation of androgen receptors expression by TNFα may represent an important regulatory mechanism required to maintain efficient spermatogenesis. M-CSF is the principal growth factor regulating macrophage populations in the testis, male accessory glands, ovary, and uterus. Both male and female M-CSF deficient (op/op) mice have fertility defects. Males have low spermatozoid number and libido as a consequence of dramatically reduced circulating testosterone. Females have extended estrous cycles and poor ovulation rates.

Normal ovarian tissue is rich in cytokines. Cytokines and chemokines are important in the physiology of ovarian function and of ovulation. Actual rupture of the follicle during ovulation may be dependent on tissue remodeling that shares some features with an acute inflammatory process. TNF and IL-1 are implicated in ovarian follicular development and atresia, ovulation, steroidogenesis, and corpus luteum function (including formation, development, and regression). Chemokines such as MCP-1 are also involved in luteolysis.

A great number of cytokines are produced by endometrium and placenta. Cytokines released at the fetomaternal interface play an important role in regulating embryo survival, controlling not only the maternal immune system but also angiogenesis and vascular remodeling. For example, LIF plays a role in the embryo pre-, peri-, and postimplantation, as does IFNτ in bovine and ovine. IFNτ is produced constitutively by embryonic trophectoderm during the period immediately prior to implantation. It acts on uterine epithelium to suppress transcription of the genes for estrogen receptor and oxytocin receptor. It blocks development of the uterine luteolytic mechanism. TGFβ is involved in regulating placental development and functions. The abortive influences of TNFα and IFNγ may terminate pregnancy during infection of uteroplacental unit. The slight dominance of proinflammatory cytokines in the fetal membranes and decidua suggest that inflammatory processes occur modestly with term labor, but much more robustly in preterm delivery, particularly in the presence of intrauterine infection.

4.6 Inflammation

"*Notae vero inflammationis sunt quatuor: rubor and tumor cum calore et dolore*" (Celsus, first century B.C.). Redness, swelling, heat, and pain are the four main parameters that characterize inflammation. They reflect the action of numerous inflammatory mediators and proinflammatory events that are orchestrated by inflammatory cytokines, mainly IL-1 and TNF, but also IL-12, IL-18, and IFNγ (Fig. 6). These cytokines are produced following

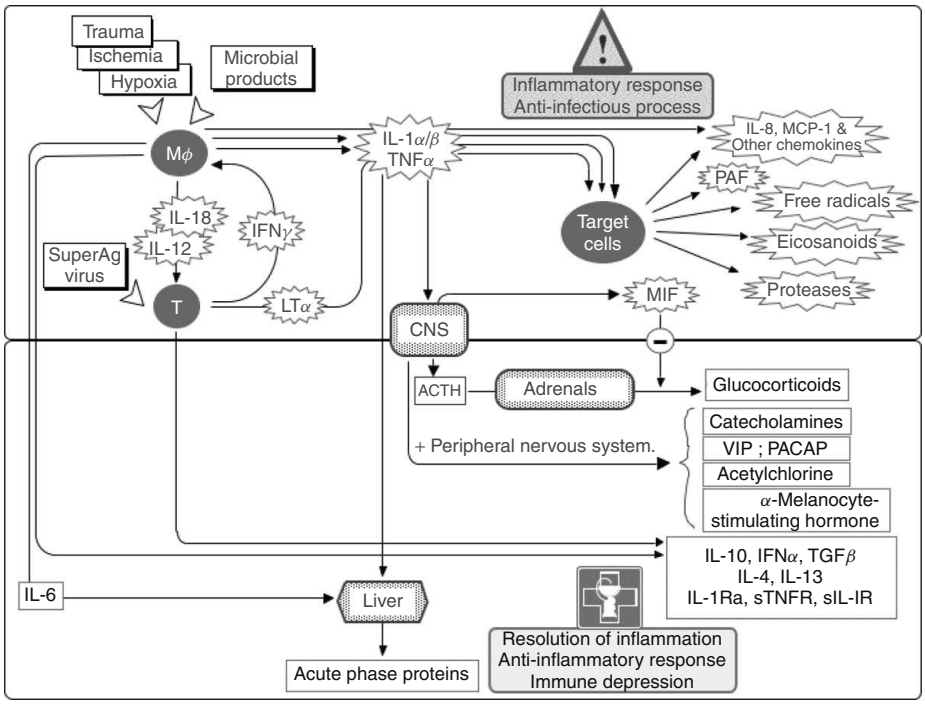

Fig. 6 Inflammation is the consequence of a cascade of events initiated by IL-1 and/or TNF. The action of these cytokines on various target cells leads to the release of numerous inflammatory mediators. Anti-inflammatory cytokines, the activation of the neuroendocrine pathway and the effects of glucocorticoids as well as the enhanced production of acute-phase proteins control negatively the inflammatory process (ACTH: adrenocorticotropic hormone; CNS: central nervous system; PACAP: pituitary adenylate cyclase-activating polypeptide; PAF: platelet activating factor; VIP: vasoactive intestinal peptide).

tissue or systemic steady state disruption like tissue loading by pathogens, ischemia, hypoxia, or trauma. Acting on target cells, they induce a cascade of mediators, including other cytokines and chemokines, proteases, lipid mediators (e.g. prostaglandins, platelet activating factor), free radicals (e.g. superoxide anion, nitric oxide) that contribute to the inflammatory process and tissue injury. Acting on endothelial cells, especially those of the postcapillary venules, they increase vascular permeability and plasma transudation, they increase circulating leukocyte adherence and margination, and they initiate the coagulation process by inducing tissue factor expression. Chemokines contribute to the recruitment of leukocytes that further maintain the inflammatory process. Some cytokines enhance the production of IL-1 and TNF (e.g. IFNγ, GM-CSF, IL-3), while others inhibit it (e.g. IL-4, IL-10, IL-13, TGFβ, IFNα). The latter contribute to attenuate the inflammatory process and to allow the tissue-repair process to occur. Other anti-inflammatory mediators include soluble IL-1 and TNF receptors, IL-1 receptor antagonist (IL-1Ra), some neuropeptides (e.g. adrenaline, acetylcholine), glucocorticoids induced after activation of the neuroendocrine loop by IL-1 and TNF,

and the acute-phase proteins produced by the hepatocytes in response to IL-1, TNF, and particularly IL-6. Acute-phase proteins contribute to eliminate debris due to cell lysis, to favor phagocytosis, to neutralize toxic mediators, and to inhibit proteases. Recently, IL-1Ra was recognized as one of the acute-phase proteins. In vivo, in the endotoxin shock model, most of these molecules have been shown to be protective.

5 Life without Cytokines (What Knockout Mice Tell Us)

Deletion of genes encoding for a cytokine or a cytokine receptor has led to the generation of many different knockout (K0) mice that further allowed to decipher the contribution of cytokines to different physiological events. In most cases, viable, fertile, and clinically healthy mice could be obtained. In few cases, the deletion of the genes led to death *in utero*, illustrating a major role of certain cytokines during embryogenesis. This was the case for SDF1 (CXCL12) and its receptor CXCR4, LIF, Cardiotrophin-1, and the gp130 chain of their receptors (see Table 3). Deletions of certain signaling molecules (e.g. STAT3) are also lethal during embryonic life. Other deletions reveal the role of certain cytokines for organogenesis during embryonic life. This is the case of lymphotoxin-α, lymphotoxin-β, and LtβR for the development of lymph nodes and Peyer's patches, and RANKL for the development of lymph nodes and mammary glands.

Tab. 3 Cytokine or cytokine receptor KO mice reveal relative contribution of cytokines to life processes.

Biological events	*Deleted gene*	*Consequences*
Embryogenesis	LIF	Absence of LIF in female prevents implantation of blastocytes
	Cardiotrophin-1 & gp130 receptor chain	Heart development blocked; death *in utero* on day 16
	SDF-1 & CXCR4	Defects in heart and brain development, intestinal vascularization, and B-cell hematopoiesis. Death *in utero*
Organogenesis	Ltα, Ltβ, LtβR	Absence of lymph nodes and Peyer's patches
	TNFα	Altered spleen and lymph node organization
	RANKL	Absence of lymph nodes, mammary gland defects
	IL-8R	Splenomegaly, lymphoadenopathy, increased circulating neutrophils
Hematopoiesis	G-CSF	Chronic neutropenia
	Stem cell factor	Absence of mast cells
	M-CSF	Altered function of monocytes and osteoclast
	IL-7	Reduced number of lymphocytes

(*continued overleaf*)

Tab. 3 (*Continued*)

Biological events	*Deleted gene*	*Consequences*
Leukocyte differentiation	Ltα, Ltβ	Absence of follicular dendritic cells
	IL-15	Absence of NK and NK-T cells
	γ-chain	Impaired B, T and NK cell development
Osteoclastogenesis	RANK & RANKL	Defect in the differentiation of hematopoietic osteoclast progenitor
Pulmonary homeostasis	GM-CSF & β-chain of GM-CSF R	Accumulation of surfactant lipids and proteins in the alveolar space. Lymphoid hyperplasia.
Gut homeostasis	IL-10	Intestinal mucosal hyperplasia, inflammatory cell infiltration, MHC Class II expression on colonic epithelium.
	IL-2	Colitis
	IL-15	Reduced intestinal epithelial B and T lymphocytes
Fever	IL-6	No pyrogenic response
Acute-phase response	IL-6	Profound alteration of acute-phase proteins production
Inflammation	TGFβ	Systemic lethal inflammation (day 24)
	IL-1-Ra	Chronic arthropathy, spontaneous dermatosis, exacerbated delayed-type hypersensitivity
	IL-5	Reduced eosinophilia
Antibody production	IL-4, IL-6, IL-13, CD40L	Altered antibody production
Immune function	IL-2, IL-4, IL-6, IL-12, IL-13, IL-15, IL-18, TNF, IFNγ, Stem cell factor, CSF, Chemokines, and their receptors.	Altered anti-infectious response

Organization of hematopoietic compartments are under the control of numerous cytokines and absence of TNFα, or the γ-chain of the receptor of IL-3, -5, -7, -9, -15, and -21 have profound perturbations on tissue organization and leukocyte differentiation. This is also true for the deletion of chemokines that contribute to tissue colonization at homeostasis. While studies of KO mice often comforted the knowledge, there were some surprises. One of them was the discovery that the absence of the hematopoietic cytokine GM-CSF did not alter hematopoiesis (mice had normal numbers of peripheral leukocytes, bone marrow progenitors, and tissue hematopoietic populations), but led to a profound alteration of the lung status, demonstrating a role of GM-CSF in pulmonary homeostasis. Of major interest was the demonstration that the deletion of anti-inflammatory cytokines (IL-10, TGFβ, IL-1Ra) was deleterious at homeostasis in the absence of experimental exogenously delivered inflammatory signals, establishing their crucial role to prevent

potential ongoing inflammatory processes at homeostasis. As expected, numerous deletions had major effects on the quality of the anti-infectious process. For example, in the absence of IL-6, mice produce lower levels of IgG antibodies against stomatitis vesicular virus, display a lower cytotoxic T-cell activity during vaccinia virus infection, leading to an increased number of virus in lungs, and failed to control *Listeria monocytogenes* load in the tissues they reached. In contrast, the same deficiencies may appear beneficial in certain experimental models of septic shock in response to endotoxin (e.g. TNFα, TNFR p55, IL-1β converting enzyme).

In humans, natural mutations occur that may affect cytokines, signaling molecules of receptors. In the latter case, the most famous mutation leads to the deletion of the γ-chain of the receptor of IL-3, -5, -7, -9, -15, and -21 and is associated with a severe combined immunodeficiency. This is for this clinical setting that occurred in 2000, the first successful gene therapy.

6 Cytokine Synthesis

6.1 Homeostasis

Owing to highly sensitive techniques (RT-PCR, *in situ* hybridization, ELISpot), it has been possible to show the presence of cytokine mRNA in various types of cells or to demonstrate the presence of cytokine-producing cells in the absence of activation. For example, IL-6 is spontaneously produced by 0.5% of bone marrow cells, 0.1% of spleen cells, and 0.01% of mesenteric lymph node cells. IL-6 is also produced in the absence of exogenous stimuli by enterocytes, eosinophils, neutrophils, epidermal cells, smooth muscle cells, bone marrow stromal fibroblasts, anterior pituitary cells, trophoblast cells, and so on. Furthermore, at homeostasis, certain cells contain cytokines. This is particularly the case for keratinocytes that contain large amounts of IL-1α. Mast cells contain a large panel of preformed cytokines (e.g. IL-1, IL-4, IL-5, IL-6, IL-13, TNF, etc), and MIF is preformed in numerous leukocytes. Furthermore, the presence of cytokines in biological fluids has been reported in absence of any infection or inflammatory diseases: IL-1α and IL-8 are found in sweat; IL-1α, IL-1β, IL-6, IL-8, GM-CSF, and TGFβ have been reported in tears; IL-2, IL-8, TNFα, TGFβ, and soluble TNFR are present in saliva; IL-2, IL-6, IL-8, IL-10, IL-12, TNF, and soluble IL-2R and IL-6R have been detected in seminal fluid; and a great number of different cytokines have been identified in human colostrum. In the later case, all of these cytokines probably act on the oropharyngeal and gut-associated lymphoid tissue of the newborn and favor the development and maturation of the immune system and may protect the newborn against invasive microorganisms delivered by the oral route. Finally, certain chemokines are present in tissues where they contribute to leukocyte recruitment at homeostasis (e.g. CCL17 & CCL25 in thymus, CCL21 & CXCL13 in lymph nodes, and Peyer's patches, CXCL12 in numerous tissues).

6.2 Induction

The production of cytokines by professional antigen-presenting leukocytes and

activated T-cells occurs during the cellular cooperation required to initiate the adaptive immunity. This production is representative of the dialogue between immune leukocytes. In contrast, innate immunity is associated with the production of cytokines in response to exogenous activators, mainly the ''pathogen associated molecular patterns'' (PAMPs). Following their interaction with the ''pattern recognition receptors'' (PRR), various intracellular signaling cascades lead to the synthesis and the release of cytokines. The best-known PRRs are the toll-like receptors (TLR) that share with IL-1R and IL-18R a homologous Toll-IL-1R (TIR) domain. Ten different TLRs have been identified so far in humans that recognize bacterial, viral, parasitic, or fungal conserved structures expressed on the surface or within the microbes (e.g. DNA, single- or double-strand RNA). Endotoxin of Gram-negative bacteria (lipopolysaccharide, LPS) is among the most potent PAMPs and picograms of this molecule are sufficient to induce the production of a whole panel of cytokines by macrophages. LPS is trapped by the CD14 molecule on the cell surface and triggers the cell via a complex MD2/TLR4. In the case of Gram-positive bacteria, some of these bacteria release exotoxins, also known as superantigens that trigger the production of cytokines by both T-lymphocytes and macrophages.

6.3 Parameters that Affect Production

In addition to the genetic polymorphism (see Sect. 8), there are numerous parameters that influence the level of the production of cytokines. Of course, *in vitro* experiments require careful sampling of the cells. The use of medium and agents free of endotoxin is very important. There are probably numerous wrong statements that suggest the capacity of a given molecule to induce the production of cytokines that are consecutive to their contamination by endotoxin, as it has been shown for heat shock proteins. *Ex vivo* studies of cytokine production by human cells is influenced by age, nutrition status, the use of drugs, alcohol, and smoking habit. Seasonal and circadian rhythms, physical exercise, altitude exposure, microgravity, social and psychological stress, physical stress, and gender affect cytokine production. In the later cases, neuromediators and sexual hormones modify cellular production of cytokines.

6.4 Measurements

The measurement of cytokines in humans can be performed in natural biological fluids, in induced biological fluids (e.g. broncho-alveolar or peritoneal lavages), on tissue biopsies, and with blood leukocytes. The detection of cytokines in biological fluids may represent the ''tip of the iceberg,'' and can be detected in the case of exacerbated production since, once produced, cytokines are efficiently trapped by their specific receptors on environmental cells. Cytokine mRNA analysis can be achieved by Northern blots, *in situ* hybridization or reverse transcriptase polymerase chain reaction (RT-PCR). Cytokine-producing cells can be monitored by ELISpot or by flow cytometry. Biological assays are not performed anymore and, nowadays, the measurement of cytokines is mainly achieved by enzyme-linked immunosorbent assays (ELISA). Cytokines constitute a tightly regulated network (see below). Thus, information concerning cytokines should be achieved through the analysis

of simultaneous quantification of several cytokines. Indeed, it is the cytokine milieu that influences the cellular response rather than the action of a single cytokine. Techniques recently available such as microarrays combined to real-time PCR or multiplex immunological detection of cytokines might give precious information in a near future.

7 The Cytokine Network

As illustrated in Fig. 7, the interactions between cytokine-producing cells and target cells lead to define a cytokine network. Once produced in the context of a specific immune response or following microbial activation, cytokines act on target cells and induce synthesis of new cytokines. The induction by IL-1 of the release of IL-2 by lymphocytes, IL-6 by fibroblasts, G-CSF by macrophages, and IL-8 by endothelial cells are examples of cytokine cascades. Cytokines can induce their own synthesis, like IL-1, or further enhance the productions, leading to amplificatory loops, like IFNγ. Another key word to define this network is synergy. Owing to the great redundancy of cytokines, two cytokines can share similar activities. When acting together on the same target cell, the effect will be far greater than the only additive effect of each individual cytokine. For example, the production of complement factor C3 by endothelial cells in response to TNF and IL-1 is far higher than that induced by these cytokines alone. The synergy may be the consequence of the induction of cytokine receptors, allowing cells to respond to a second cytokine they would not do normally because they lack the specific receptor. The network also involves negative loops as a consequence of the action of cytokines, blocking the production or the effects of others. IL-10 is an example of a cytokine blocking the production and the action of other cytokines. However, the lineage of its target cell may lead to opposite observations. For example, IL-10 represses LPS-induced IL-8

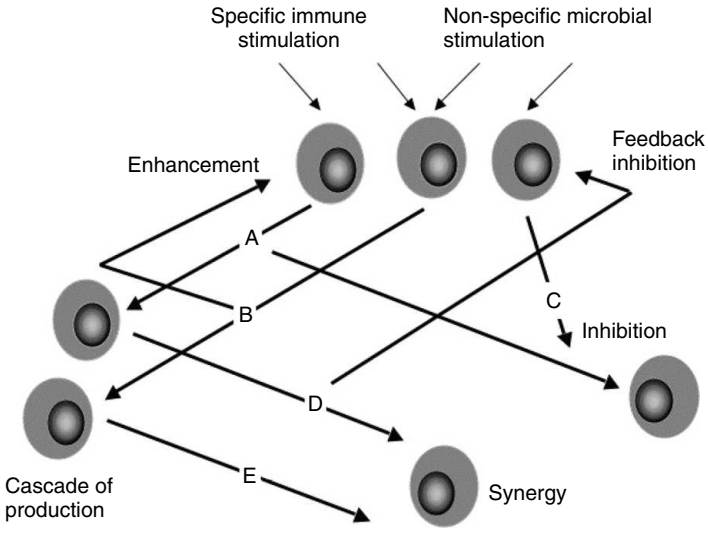

Fig. 7 The cytokine network (see Sect. 7).

production by monocytes, but enhances that produced by endothelial cells.

8 Individual Heterogeneity

Among genetic predisposition to diseases, premature death due to uncontrolled invasion and growth by microorganisms has the higher relative risk linked to heritability. The individual heterogeneity reflects in part genetic polymorphisms of cytokines. Three levels can be dissociated (Fig. 8) as follows:

1. A genetic polymorphism exists for the receptors of PAMPs. These sensors are the first essential elements in initiating an intracellular signaling cascade that leads to cytokine production. Certain single nucleotide polymorphisms (SNP) or mutations can directly modify the intensity of the responsiveness and influence disease susceptibility, as recently shown by the existence of rare mutations of TLR4 among patients with meningococcal infection.
2. SNP or mutations can affect cytokine genes, particularly when expressed within gene promoters or other regulatory sequences. Accordingly, high, intermediate, or low producers are reported when assessing the levels of cytokines produced in response to an activator. Correlation between TNF genotypes and levels of released TNF in response to LPS has been shown.
3. Finally, depending upon the donors, target cells can react intensively, moderately, or weakly to a given amount of a cytokine. This has been nicely demonstrated with genetically distinct endothelial cells, which express various levels of adhesion molecules in response to similar amounts of IL-1 or TNF. In all these situations, the genetic polymorphism could also reflect SNP or mutations among the genes of the adaptors and signaling molecules involved in the signaling cascades.

As illustrated in Table 4, numerous cytokine gene polymorphisms have been associated with the occurrence or severity of diseases. The reported SNP or mutations can be associated with a protection against the disease or in contrast with a higher susceptibility. More recently, similar gene polymorphisms have been associated with the efficiency or the lack of efficiency of certain therapeutic approaches, particularly when the treatment targets cytokines.

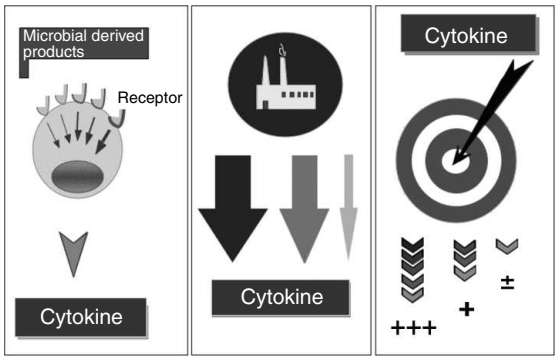

Fig. 8 Individual heterogeneity for cytokine production and responsiveness.

Tab. 4 Some examples of cytokine or cytokine receptor gene polymorphisms associated with diseases.

Disease	*Gene polymorphism*
Acute renal failure mortality	TNF, IL-10
Allergy	RANTES promoter; MIF promoter; IL-13 promoter IL-16 promoter; IL-1 gene complex; IL-18; IL-12B promoter
Asthma	IL4R α-chain; IL-10; IL-15; IL-18; TGFβ1 promoter; Eotaxin
Alzheimer	IL-1α, TNFR2, IL-6
Breast cancer	IL-6
Chronic periodontitis	IL-10 promoter, IL-1B +3953 and TNF-A-308 allele 2 positive
Coronary disease	IL-1Ra
Crohn's disease	IL-10, MCP-1 (CCL2); IL-16 promoter; TNFR1
HIV resistance	CCR5 deletion
Idiopathic pulmonary fibrosis	TNF-alpha (-308 A) allele
Infectious nephropathy	low CXCR1 expression
Infertility	functional mutations in the LIF gene
Lupus nephritis	MCP-1 (CCL2) promoter
Multiple sclerosis	microsatellite allele of TNF gene; IL-2 promoter
Parkinson's disease	promoter region of IL-8
Rheumatoid arthritis	noncoding region of IFNγ gene; TGFβ1; MIF promoter; IL-1 gene cluster; IL-4
Schizophrenia	IL-1 gene complex
Sepsis mortality	TNF
Systemic lupus erythematosus	IL-1α; TNFα
Sudden infant death syndrome	IL-10
Susceptibility to cerebral malaria	TNF
Transplantation	TNF, IL-10

9
Cytokines and Infections

9.1
Half Angel–Half Devil

As mentioned in Sect. 4.2.1, cytokines play a major role in innate immunity during the early processes that occur in sites of microorganisms' invasion. During viral infection, the antiviral properties of interferons have been established for more than half a century. After interaction of IFNα or IFNβ with its receptor, the activation of 2–5 A synthetase leads to the production of an endoribonuclease that degrades viral RNA, while activation of protein kinase P1 contributes to the capacity of the cell to inhibit viral protein synthesis. During bacterial infection, the beneficial effects of proinflammatory cytokines have been widely demonstrated. The injection of cytokines such as IL-1, IL-6, IL-12, IL-18, TNF, G-CSF, M-CSF, GM-CSF, and IFNγ before the injection of bacteria have been shown to promote faster clearance of bacteria, and to enhance survival. The use of cytokine-neutralizing antibodies or antagonists molecules further demonstrated that endogenous cytokines produced in the course of infections play an essential role in preventing the microorganisms to establish themselves, or to grow, and their neutralization was highly deleterious. Finally, mice rendered deficient for the expression of a cytokine or a cytokine

receptor display enhanced "susceptibility" to infection such as an enhanced microbial load in tissues, and reduced survival.

Despite their undoubtedly beneficial effects to clear microorganisms, some cytokines can also contribute to death in some clinical situations like the septic shock in response to endotoxin injection or after a lethal bacterial infection. Antibodies against TNF protect mice against lethal injection of LPS and baboons against lethal injection of *E. coli*. The ambivalent role of cytokines is illustrated in TNF receptor p55 knockout mice: these mice are more sensitive to *L. monocytogenes* infection than normal mice, but they are more resistant to toxic shock induced by endotoxin or Staphylococcal enterotoxin B. Furthermore, the synergy already described as a key word to define cytokine network is also valid for lethality and none lethal dose of TNF, injected with non-lethal dose of IL-1 or IFNγ leads to lethality in mice.

9.2 The Strategies of Microbes against Cytokines

The fact that pathogenic microorganisms have developed numerous subterfuges to counteract the action of cytokines further illustrates that cytokines are crucial in the fight against the infectious process. Hijacking of genes for cytokine receptors has been perpetrated by virus to elaborated soluble molecules that neutralize cytokines of the host (e.g. IFNγR and TNFR homologs of Myxoma virus, IL-1R homolog of Vaccinia virus). Another hijacking concerns the gene of IL-10, allowing viruses (Epstein–Barr virus, equine herpesvirus, parapoxvirus orf virus) to create an immunosuppressive environment. Another strategy has been developed by Vaccinia virus to prevent the maturation of biologically active IL-1 and IL-18. This virus produces an inhibitor (serpine) of caspase-1, the enzyme required for the cleavage of the proforms of these cytokines. Other mechanisms include the production of viral factors that downregulate cytokine mRNA expression (e.g. HTLV, adenovirus), the use of cytokines to further enhance the viral replication (e.g. HIV), the use of chemokine receptors to enter the cell (e.g. HIV), or the synthesis of viral chemokines that can behave as antagonists (e.g. Kaposi' sarcoma associated virus, human Herpesvirus 8, Steakth virus, etc.). Bacteria also display strategies to block cytokine production (e.g. *Yersinia enterocolitica*, enteropathogenic *E. coli*) and to use them as growth factors (*Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Acinetobacter*).

10 Cytokines and Diseases

As the discovery of new cytokines were occurring, great hopes to cure diseases were mentioned, often followed by great disappointments. For example, while TNF was discovered for its antitumor effect, it was soon demonstrated that it was one of the most potent proinflammatory cytokines, obviously limiting its therapeutic use. One unique cytokine is rarely the unique key effector underlying the pathogenic process, and the complexity of the cytokine network has rendered difficult their use as therapeutic tools or as therapeutic target. In addition, the identification of an overexpressed cytokine at one peculiar stage of the disease process does not allow discriminating whether this cytokine is a marker or an actor. Nevertheless, there exist certain clinical situations in which the use of recombinant cytokines or the use of

neutralizing antibodies has allowed significant therapeutic progresses. Few examples of diseases for which the involvement of cytokines is well established and clinical applications have been considered are summarized below.

10.1 Autoimmune Diseases

Among autoimmune diseases, systemic lupus erythematosus has been associated with an exacerbated production of IL-10. Considering the properties of IL-10, which activates B-lymphocytes and inhibits T-lymphocytes, its overproduction in lupus could explain the immune anomalies of this disease, which is characterized by anti-self antibodies production and by deficient T-responses. Thus, the use of IL-10 antagonists may be beneficial in the management of systemic lupus erythematosus, as suggested by a preliminary report. Human lupus patients also have elevated blood levels of BAFF that support differentiation of selected B-cells into mature long-lived B-cells and may be critical in generating deleterious autoimmune responses. Indeed, overexpression of BAFF in mice may lead to systemic lupus erythematosus–like disease. Thus, BAFF could be another potential cytokine to neutralize in systemic lupus erythematosus.

10.2 Allergy

Allergen specific IgE antibodies, mast cell degranulation releasing inflammatory mediators such as histamine, and influx of eosinophils in airway mucosa and airway lumen are a hallmark of atopy and allergic asthma. Thus, Th2 cytokines remain important candidates for a role in the pathogenesis of atopy and allergic asthma: IL-4 and IL-13 are required for IgE production, IL-9 is involved in mast cell growth, and IL-5 is required for eosinopoiesis. Humanized monoclonal antibodies (hMAbs) against IL-5, anti-IL-4, a recombinant soluble human IL-4 receptor, anti-IL-9, CCR3 antagonists (which block eosinophil chemotaxis), and CXCR2 antagonists (which block neutrophil and monocyte chemotaxis) have been developed as possible therapeutic interventions.

10.3 Sepsis

Animal models of sepsis have clearly shown that TNF, IL-1, or MIF are involved in sepsis-related lethality, and antibodies against these cytokines are highly protective. Unfortunately, anti-TNF antibodies and IL-1Ra have been used in numerous placebo double-blinded controlled assays in humans without any success. This failure may reflect that antibodies in animal models and in humans are not used with similar timings, and that mice, often used in experimental models, being 10^5 less sensitive to Gram negative bacteria–derived endotoxin than humans, are not the most relevant laboratory animals to model the human settings!

10.4 Chronic Inflammatory Diseases

Fortunately for companies that had developed these anti-TNF antibodies, successful treatments have been achieved for Crohn's disease and rheumatoid arthritis. The significant improvement of patients allowed the marketing of these antibodies. However, in none of these studies,

the successful improvement concerned all patients. For rheumatoid arthritis, the first successful treatment was reported in 1994. In responding patients, clinical improvements were associated with biological changes, reflecting the attenuation of the inflammatory process. There was no clinical response in 30% of the cases. While the effect of a single injection is long lasting (few months), it has to be repeated. As a consequence, the occurrence of microbial pathogenic processes (tuberculosis, *Pneumocystis*- triggered pneumonia, histoplasmosis, listeriosis, sepsis) has been deplored. Other approaches have been proposed to neutralize TNF with recombinant soluble TNF receptors. IL-1Ra has also been approved by the Food and Drug Administration (FDA) for treatment of rheumatoid arthritis. For this disease, the targeting of IL-17 has also been suggested to be of potential value. For Crohn's disease, the anti-TNF treatment was approved in 1998, and clinical response was still observed 12 weeks after the infusion. A remission could be obtained for half of the patients after 4 doses every 8 weeks.

10.5 Cancer

IL-2 has been extensively studied in cancer patients, either alone, or associated with chemotherapy, with activated NK cells (Lymphokine-activated killer cells, LAK), with tumor-infiltrating lymphocytes (TIL), with IFNα, and, more recently, with tumor-pulsed dendritic cells. In some specific cases (melanoma, metastatic renal cancer), success remained modest. The major achievement has been obtained with IFNα in hairy cell leukemia and chronic myelogenous leukemia.

10.6 Hepatitis C

IFNα has been successful in a subset of hepatitis C virus–infected patients. More recently, once associated to ribavirin, a polymerized form of IFNα, the half-life of which is prolonged, has been shown to lead to sustained virological response rates of $>50\%$ in chronic hepatitic C patients.

10.7 Multiple Sclerosis

In 1993, interferon-β was approved in the United States for relapsing–remitting multiple sclerosis. The use IFNβ and glatiramer acetate for the treatment of multiple sclerosis has, to some extent, changed the course of the disease. The annual relapse rate of patients treated with these drugs is lower than that in placebo-treated patients, and more treated patients remain relapse-free as compared to untreated patients.

10.8 Transplantation

The alpha-chain of the IL-2R is a specific peptide against which monoclonal antibodies have been raised, with the aim of blunting the immune response by means of inhibiting proliferation and inducing apoptosis in primed lymphocytes. One of such antibodies has proved to be effective in reducing the episodes of acute rejection after kidney and pancreas transplantation. The use of this antibody was associated with a significant reduction in the incidence of any treated rejection episodes after kidney transplantation in the two major randomized European and US studies.

10.9 Neutropenia

Following chemotherapy for leukemia, neutropenia renders the patients more susceptible to develop infection. Treatment of patients with G-CSF and GM-CSF accelerates the recovery of normal neutrophil counts and significantly reduces the occurrence of documented infections.

11 Conclusion

Despite the huge number of molecules that belong to the cytokine family, the complexity of the cytokine network, the great number of parameters that may affect the biological properties of cytokines, tremendous amount of work has allowed to decipher the language of cells. Despite the difficulty, new promising use of cytokines or cytokine antagonists can be expected to master certain diseases.

Keywords

Cytoskeleton
A dynamic network of protein tubules (microtubules) and filaments (microfilaments and intermediate filaments) in all eukaryotic cells that is necessary for cell shape, cell motility, and spatial and temporal organization of molecules, and organelles within the cells.

Microtubules
Long hollow cylindrical tubes with an external diameter of 24 nm that are formed by polymerization of α- and β-tubulin monomers.

Microfilaments
Filaments of about 7-nm diameter that are formed by polymerization of actin.

Kinesins
A family of motor proteins in eukaryotes that can hydrolyze ATP and use the derived energy to either transport organelles, vesicles, and RNA protein complexes on microtubules or regulate microtubule dynamics.

Myosins
A family of motor proteins that can hydrolyze ATP and move on microfilaments. These motors function in muscle contraction, cell division, and vesicle transport.

Preprophase Band
A narrow band of interconnected microtubules and microfilaments encircling the nucleus that appears in cells preparing to enter mitosis and marks the location of future cell wall.

Phragmoplast
A plant-specific structure made of two discs of microtubules (and microfilaments) that is formed between two daughter nuclei at late telophase. It constructs the new cell wall between the daughter nuclei.

Trichome
A hair-like branched or unbranched structure on the surface of a leaf or stem. These structures may be unicellular or multicellular.

Molecular motors regulate diverse cellular functions, including the organization and dynamics of the microtubule (MT) and actin cytoskeleton, cytoplasmic streaming, cell polarity, cell growth, morphogenesis, chromosome segregation, and transport of vesicles, organelles, and macromolecular complexes. In eukaryotes, there are three families of molecular motors: the kinesins, the dyneins, and the myosins. All three types of motors use ATP to move along filamentous structures. Kinesins and dyneins move on MTs, whereas the myosins translocate on actin filaments. Using

biochemical, cell biological, molecular, and genetic approaches, several molecular motors have been identified in plants, and functions of some of these are beginning to be understood. Recent completion of genome sequence of several eukaryotes ranging from yeast, a simple unicellular eukaryote, to highly evolved multicellular organisms, including humans and flowering plants, has permitted comparative analysis of three families of motors in various species. Such analysis across phylogenetically divergent species has yielded some interesting insights into evolutionary and functional relationships among motor proteins from various organisms. Systematic analyses of the recently completed Arabidopsis genome sequence with the conserved motor domain of kinesins, myosins, and dyneins revealed the presence of 78 molecular motors (61 kinesins and 17 myosins) in this organism. Of the two families of MT-based motors, dyneins are absent in Arabidopsis. Surprisingly, Arabidopsis has the largest number of kinesins as compared to other multicellular organisms including humans, suggesting that the kinesin superfamily is expanded considerably in plants. Also, all plant myosins belong to two novel classes. Although the identification of molecular motors in plants is progressing rapidly due to genome and EST-sequencing projects, only a few plant motors have been characterized in any detail and the functions of many these motors are not known. Nevertheless, it is becoming obvious that plants contain novel families of kinesins and myosins with unique functions and regulatory mechanisms. In this article, the focus is primarily on plant molecular motors, their function, and regulation with emphasis on model plant Arabidopsis.

1
Microtubule-based Motors

The motors that move on MTs (microtubules) belong to two different families: kinesins that move either toward plus end or minus end of the MTs, and the dyneins, which move toward the minus end of MTs.

1.1
Kinesins

Members of the kinesin superfamily are known or implicated to play important roles in many fundamental cellular and developmental processes, including intracellular transport of vesicles and organelles, mitotic and meiotic spindle formation and elongation, chromosome segregation, germplasm aggregation, MT organization, and dynamics and intraflagellar transport. A large number of kinesins have been identified in plants and animals (Table 1). All members of the kinesin superfamily have a highly conserved catalytic region of about 350 amino acid residues, known as the *motor domain*, with ATP- and MT-binding sites. The motor domain in kinesins is located either in the N-terminus, C-terminus, or in the middle of the protein. In addition to the motor domain, most kinesins have a stalk region that forms an alpha-helical coiled-coil region, which aids in dimerization, and a highly variable tail, which is thought to interact with a specific cargo.

Although molecular motors have been implicated in a variety of cellular processes

in plants, including spindle function, cytokinesis, cell polarity, morphogenesis, organelle and vesicle transport, and cytoplasmic streaming, until recently very little was known about their molecular identity. Plant kinesins have been identified in pollen tubes of tobacco and other plants using antibodies to animal kinesins. An MT-based motor (90 kD) from tobacco pollen tubes, which induced MT gliding in motility assays, binds organelles associated with MTs in the cortical regions of the pollen tube, suggesting its involvement in organelle transport. Two kinesins (125 kD and 120 kD) that showed plus-end motor activity in *in vitro* motility assays and MT-dependent ATPase and GTPase activity were isolated from tobacco phragmoplasts. Using various approaches, cDNAs for several kinesins have been characterized from plants. Thirteen of these are from Arabidopsis (KatA, KatB, KatC, KatD, AtKCBP, AtPAKRP1, AtPAKRP1L, AtPAKRP2, AtMKRP1, AtMKRP2, AtNCAK1, KCA1, KCA2), 15 from tobacco (TKRP125, KCBP, NCAK1, NCAK2, and TBK1 to TBK11), and 1 from potato (KCBP). A kat gene family (katA, katB, katC, katD, and katE) encoding kinesins in *Arabidopsis thaliana* was characterized using primers corresponding to conserved regions of the kinesin motor domain. Using a similar approach, 12 different kinesins that belong to seven subfamilies have been isolated from tobacco BY-2 cells. It is interesting that in tobacco BY-2 cells alone 15 different kinesins that belong to different subfamilies are expressed. KatA (89 kD) protein has been shown to be a minus-end-directed motor, and a similar protein has been found in carrot and tobacco. KatA (new name ATK1) is necessary for bipolar spindle assembly during male meiosis. The central region of KatD shares sequence similarity to the motor domain of kinesin and is followed by about 240 residues at the C-terminus. Phylogenetic analysis with the katD motor domain indicates that it belongs to the C-terminal family despite the fact that it has a 240 amino acid stretch following the motor domain. The amino-terminal region of katD showed sequence similarity to the calponin homology (CH) domain. KatD is a flower-specific motor protein, suggesting that it may function in transport or cytoskeleton organization in pollen. TKRP125 (tobacco kinesin–related polypeptide of 125 kD) is an N-terminal kinesin with strong similarity to members of the BimC (blocked in mitosis) subfamily. Two other members of BimC class kinesins (DcKRP120-1 and DcKRP120-2) were isolated from carrot suspension cells. DcKRP120-1 is a homolog of TKRP125. In Arabidopsis, there seem to be at least three TKRP-like proteins. Recently, three phragmoplasts-associated kinesin-related proteins (AtPAKRP1, AtPAKRP1L, and AtPAKRP2) have been isolated and characterized from Arabidopsis. AtPAKRP1 is an N-terminal kinesin and is most closely related to

XKlp2, an ungrouped kinesins from *Xenopus laevis*. AtPAKRP2 is also an N-terminal motor with no known homologs in nonplant systems. In phylogenetic analysis, AtPAKRP2 does not group with any of the existing families of kinesins. These motors have distinct functions in cytokinesis. The AtPAKRP1L that is closely related to AtPAKRP1 shows same localization as AtPAKRP1, suggesting that these two kinesins may have a similar role in cell division.

KCBP (kinesin-like calmodulin-binding protein), a novel kinesin with a C-terminal motor domain, was isolated from a number of plants as a calmodulin-binding protein. Although KCBP, like other kinesins, contains three distinct regions (a motor domain, a coiled-coil stalk, and a tail), it has two features that make it unique among members of the kinesin superfamily in eukaryotes. These include (1) a calmodulin-binding domain adjacent to the motor domain at the C-terminus and (2) a myosin tail homology and talin-like region in the N-terminal tail. KCBP binds calmodulin in a calcium-dependent manner at physiological calcium concentrations. KCBP is a minus-end directed MT motor and has two MT-binding domains, one located at the C-terminus and the second one located at the N-terminus. Unlike the MT-binding domain in the C-terminus, the N-terminal region of KCBP binds MTs, both in the presence and absence of ATP, indicating that the MT-binding domain in the N-terminus is insensitive to ATP. KCBP is highly conserved in phylogenetically divergent plant species, including dicots, monocots, gymnosperms, and algae. Recently, a calmodulin-binding C-terminal kinesin (kinesin C) was cloned from sea urchin. The calmodulin-binding domain of kinesin C shared 35% sequence identity with the calmodulin-binding domain in KCBP. The existence of calmodulin-binding kinesins in both plants and sea urchins suggests that the origin of this group of kinesins predates the divergence of plants and animals from a common ancestor, which is believed to have occurred about 1.5 billion years ago. If this was the case, there must have been insertion of some domains such as MyTH4 and talin-like regions in the tail of KCBP (or deletion of these domains in kinesin C) to acquire functional specialization of these kinesins. Alternatively, calmodulin-binding kinesins may have evolved independently in plant and animals after they diverged from a common ancestor. The amino-terminal tail and stalk regions of KCBPs from different plant systems are highly conserved and contain myosin tail homology (MyTH4) and talin-like regions that are not present in kinesin C. In phylogenetic analysis of kinesins, KCBPs and kinesin C are grouped with other known C-terminal kinesins. However, Arabidopsis KCBP together with its orthologs from other plants constitute a distinct group within the C-terminal subfamily of motors.

Recently, two Arabidopsis kinesins (AtMKRP1 and AtMKRP2) with mitochondrial targeting signals were found to be targeted to mitochondria, suggesting that these motors might function in this organelle. AtMKRP1 and AtMKRP2 belong to ungrouped kinesins. What functions these MKRPs perform in mitochondria remains to be seen. There are other Arabidopsis kinesins with targeting signals to other organelles such as chloroplasts. It would be interesting to see if any other Arabidopsis kinesins are targeted to organelles. Kinesins that are targeted to organelles have not been reported previously in the literature.

Mutations in the *HINKEL* (*HIK*) gene in Arabidopsis result in defective cytokinesis. These mutants have high frequency of incomplete cell walls and multinucleate cells. The *HIK* gene encodes a plant-specific N-terminal kinesin that plays an important role in cytokinesis. Two tobacco kinesins (NACK1 and NACK2) interact with NPK1, a mitogen-activated kinase kinase kinase, and stimulate the activity of the kinase. Orthologs of NACK1 and NACK2 have been identified in Arabidopsis and AtNACK1 was found to be identical to HIK. These kinesins are highly diverged N-terminal motors and do not group with any of the known kinesin subfamilies. The closest nonplant kinesin that shares significant similarity with the motor domain of NACKs is CENP-E. At least eight Arabidopsis kinesins are known to function in some aspect of cell division (see Sect. 3.1 on cell division).

Analysis of the recently completed Arabidopsis genome sequence with the conserved motor domain of kinesins has resulted in identification of 61 kinesins in the model plant. A corresponding cDNA or EST (expressed sequence tag) was found for most kinesins, suggesting that most kinesins in Arabidopsis are expressed and not likely to be pseudogenes. The genes encoding kinesins are distributed throughout the genome. Chromosome 3 has the highest number (18) of kinesin genes. In comparison, *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Caenorhabditis elegans*, *Drosophila*, and *Homo sapiens* have 6, 9, 21, 24, and 45 kinesins respectively (Table 1). Surprisingly, the Arabidopsis genome contains the largest number of kinesins among all eukaryote genomes that have been sequenced. Arabidopsis has the highest percentage (0.24%) of the total number of genes as compared to *S. cerevisiae* and *S. pombe* with 0.1% and 0.17% respectively, *C. elegans* with 0.11%, and *Drosophila* with 0.18%. On the basis of the number of kinesins in Arabidopsis, the number of cellular processes that is regulated by kinesins in plants is likely to match or exceed the number of processes controlled by animal kinesins.

Only 13 of the 61 Arabidopsis kinesins have been reported in the literature, whereas the 3 AtKRP125 kinesins (AtKRP125a,b,&c; Table 2) show sequence similarity to a tobacco kinesin (NtKRP125) that was isolated from phragmoplasts of tobacco. AtKRP125b has 68% identity with NtKRP125 over the 1000 residues they have in common.

The number of known and predicted introns in kinesins ranges from 3 to 34 (Table 2). In the Arabidopsis genome, the number of introns ranges from 0 to 77 with an average of about 5. More than 85% of Arabidopsis genes have 10 or less introns, while the Arabidopsis kinesin genes have an average of 16.4 with only 10 genes having 10 or less introns. The number and locations of the introns need to be verified experimentally. It is likely that the predicted sizes of the proteins in Tables 2 and 3 may change somewhat as corresponding cDNAs are characterized. In a few cases in which the cDNAs were isolated recently, there are some differences between the predicted and actual size of the protein due to inaccurate predictions of introns and exons.

All Arabidopsis kinesins except three have a coiled-coil region, suggesting that they may function as homo or heterodimers (Fig. 1 and Table 2). Interestingly, some Arabidopsis kinesins have predicted domains that are not present nonplant kinesins (Fig. 1, Table 2). Six of the Arabidopsis kinesins have a calponin homology (CH) domain, which is an actin-binding domain present in the N-termini

[e] NCBI predicted protein has 1662 amino acids.
Notes: The number of amino acids in parenthesis are based on the deduced number from cDNA. CC: coiled coil; CH: calponin homology domain; MyTH4: domain present in the tail region of some myosins; Talin-like: talin-like domain found in some myosins and band 4.1 superfamily; CBD: calmodulin binding domain; PEST: motif rich in proline, glutamine, serine, and threonine residues; ARM: Armadillo/beta-catenin-like repeats; HhH1: helix-hairpin-helix.
(Modified from Reddy, A.S.N., Day, I.S. (2001a) Analysis of the myosins encoded in the recently completed *Arabidopsis thaliana* genome sequence, *Genome Biol.* **2**, 24.21–24.17).

of spectrin-like proteins. The CH domain is a protein module of approximately 110 residues found in cytoskeletal and signal transduction proteins, either as two domains in tandem or as a single copy. Proteins with a tandem pair of CH domains cross-link F-actin, bundle actin, or connect intermediate filaments to cytoskeleton. Proteins with a single copy are involved in signal transduction. Perhaps the kinesins containing a CH domain bind actin and are involved in signal transduction or linking of actin and MTs. Some domains that are involved in protein–protein or protein–DNA interactions are also present in some kinesins (Fig. 1 and Table 2). These include armadillo repeats, a helix-hairpin-helix DNA-binding domain. KCBP has MyTH4 and talin-like domains present in some myosins, suggesting that it has domains of both MT- and actin-based motors. Such motors may be involved in cross talk between MT and actin cytoskeleton. KCBP also has been shown to have a calmodulin-binding domain.

1.1.1 Phylogenetic Analysis

In nonplant systems, nine subfamilies of kinesins with some ungrouped kinesins have been identified by phylogenetic analysis using the conserved motor domain. Three of the subfamilies (KHC, KRP85/95, and Unc104/KIF1) are involved in transport. Members from the other subfamilies (C-terminal, Kip3, MKLP1, BimC, chromokinesin/KIF4, and MCAK/KIF4) function in various processes associated with cell division. A phylogenetic analysis of the 61 Arabidopsis kinesins motor domain sequences with 113 other motor domain sequences from nonplant systems has revealed that seven of the nine families are represented in Arabidopsis (Figs. 2 and 3). However, several Arabidopsis kinesins do not fall into any of the nine subfamilies and are likely to represent

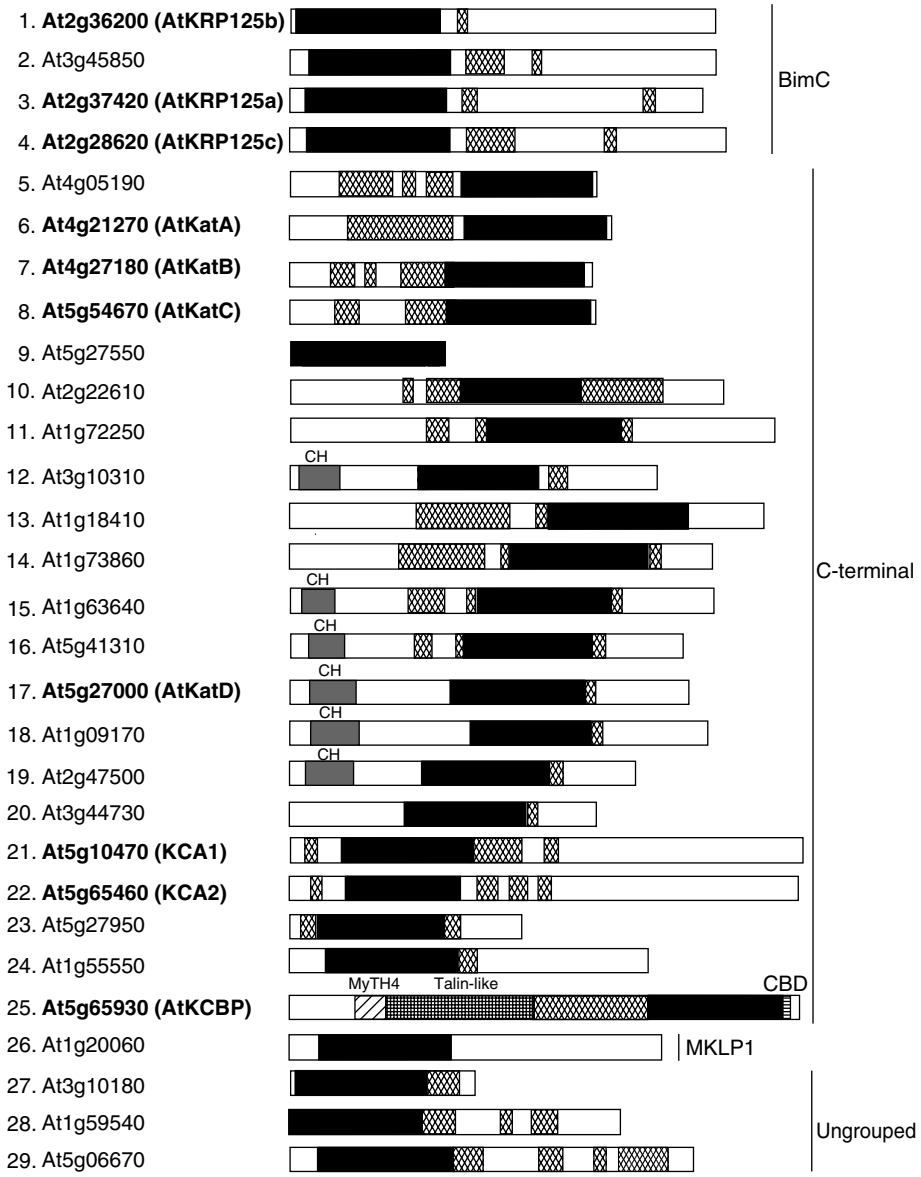

Fig. 1 Structural features of Arabidopsis kinesins. The deduced amino acid sequence of kinesins in the Arabidopsis database was analyzed for the presence of various domains. The kinesins are arranged according to their grouping in the phylogenetic tree in Fig. 3. Characterized kinesins are indicated in bold. ARM, Armadillo/beta-catenin-like repeat, CBD, calmodulin-binding domain; CC, coiled-coil region; CH, Calponin homology domain; MD, motor domain; MyTH4, myosin tail homology region; Talin-like, talin-like domain; HhH1, helix-hairpin-helix domain. Fig. 1 (*Continued*)

additional subfamilies that are unique to plants (Figs. 2 and 3). Most of the Arabidopsis kinesins are more closely related to another Arabidopsis or another plant kinesin than to any other kinesin used in the comparison. The subfamilies that are involved in transport are underrepresented in Arabidopsis (Fig. 2). There are no members of the KRP85/95 or Unc104/KIF1 subfamilies in Arabidopsis (Figs. 2 and 3). No KHCs have been reported in plants. The phylogenetic tree indicates that there is possibly one KHC-type kinesin in Arabidopsis. At3g63480

(Modified from Reddy, A.S.N., Day, I.S. (2001a) Analysis of the myosins encoded in the recently completed *Arabidopsis thaliana* genome sequence, *Genome Biol.* **2**, 24.21–24.17).

falls into the KHC group with a closer relationship to KHCs found in fungi and, like fungal KHC, lacks binding site for kinesin light-chain proteins. However, biochemical and functional studies are needed to verify that At3g63480 codes for a KHC. One Arabidopsis kinesin groups with the MKLP1 subfamily (Fig. 3). Two internal motor Arabidopsis kinesins grouped with the MCAK/KIF2 subfamily (also called *the internal family*), whose members are involved in vesicle transport, chromosome movement, and MT catastrophe. Three Arabidopsis kinesins fall into a group with Kip3 subfamily members in which ScKip3 is involved in nuclear movement. Three Arabidopsis kinesins form a branch off of the chromokinesin/KIF4 subfamily members, some of which are involved in vesicle transport (HsKIF) and spindle organization and chromosome positioning (Xlklp1). Arabidopsis has many kinesins (24 out of 61) that did not fall into any of the known groups (Figs. 2 and 3). Members of BimC subfamily, which are N-terminal plus-end motors, are present in all five eukaryotic organisms that have been sequenced. The three NtKRP125-like

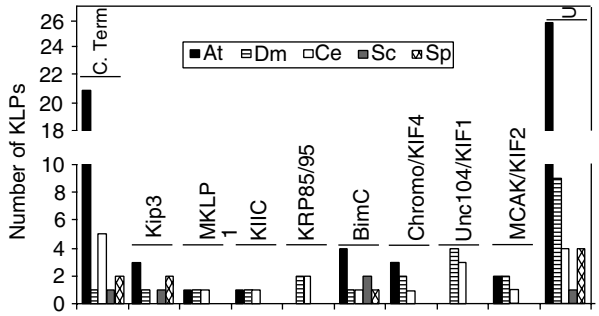

Fig. 2 The number of kinesins in each family in different organisms. C.Term, C-Terminal motor; Chromo/KIF4, chromokinesin/KIF4; U, ungrouped. At, *Arabidopsis thaliana*; Dm, *Drosophila melanogaster*; Ce, *Caenorhabditis elegans*; Sc, *Saccharomyces cerevisiae*; Sp, *Schizosaccharomyces pombe* (Adapted from Reddy, A.S.N., Day, I.S. (2001b) Kinesins in the Arabidopsis genome: A comparative analysis among eukaryotes, *BMC Genomics* **2**, 2.1–2.13).

Arabidopsis kinesins (AtKRP125a, b, and c) are grouped with the tobacco homolog in the BimC subfamily, which are involved in cross-linking and antiparallel sliding of MTs.

Twenty-one Arabidopsis kinesins were grouped into the C-terminal subfamily. This is an unusually large number compared to the other organisms. It is also unusual in that 11 kinesins in this group have internal motors and five have N-terminal motors. The internal kinesins have a motor domain that is closer to the C-terminus than the N-terminus, but each has some sequence C-terminal to the motor domain and could be called internal, depending on the parameters used to define an internal motor. It will be interesting to find out the direction of movement of these kinesins whose motor domains are either N-terminal or internal, but are most closely related to the C-terminal subfamily. Kinesins in the C-terminal subfamily translocate toward the minus end of MTs and have a conserved sequence at the neck/motor core junction. It was reported that the residues G and N residues at the neck/motor core junction are necessary for minus-end directed movement. Analysis of the neck/motor core junction of the 21 C-terminal class Arabidopsis kinesins showed conservation of these residues in most of the C-terminal Arabidopsis kinesins.

Several Arabidopsis kinesins show some similarity to other ungrouped kinesins (Figs. 2 and 3). The ungrouped centromeric proteins (HsCENPE and UmKin1) cluster with seven Arabidopsis kinesins. CENP-E binds to the kinetochore throughout mitosis and to MTs of the spindle midzone during late stages of mitosis. One Arabidopsis kinesin is paired with HsKid, an ungrouped kinesin. HsKid is a kinesin-like DNA-binding protein that is involved in spindle formation and the movements of chromosomes during mitosis and meiosis. Arabidopsis PAKRP1 along with five other Arabidopsis kinesins are grouped with XlKlp2. XlKlp2 is required for centrosome separation and maintenance of spindle bipolarity, whereas PAKRPs associates with the phragmoplast and is

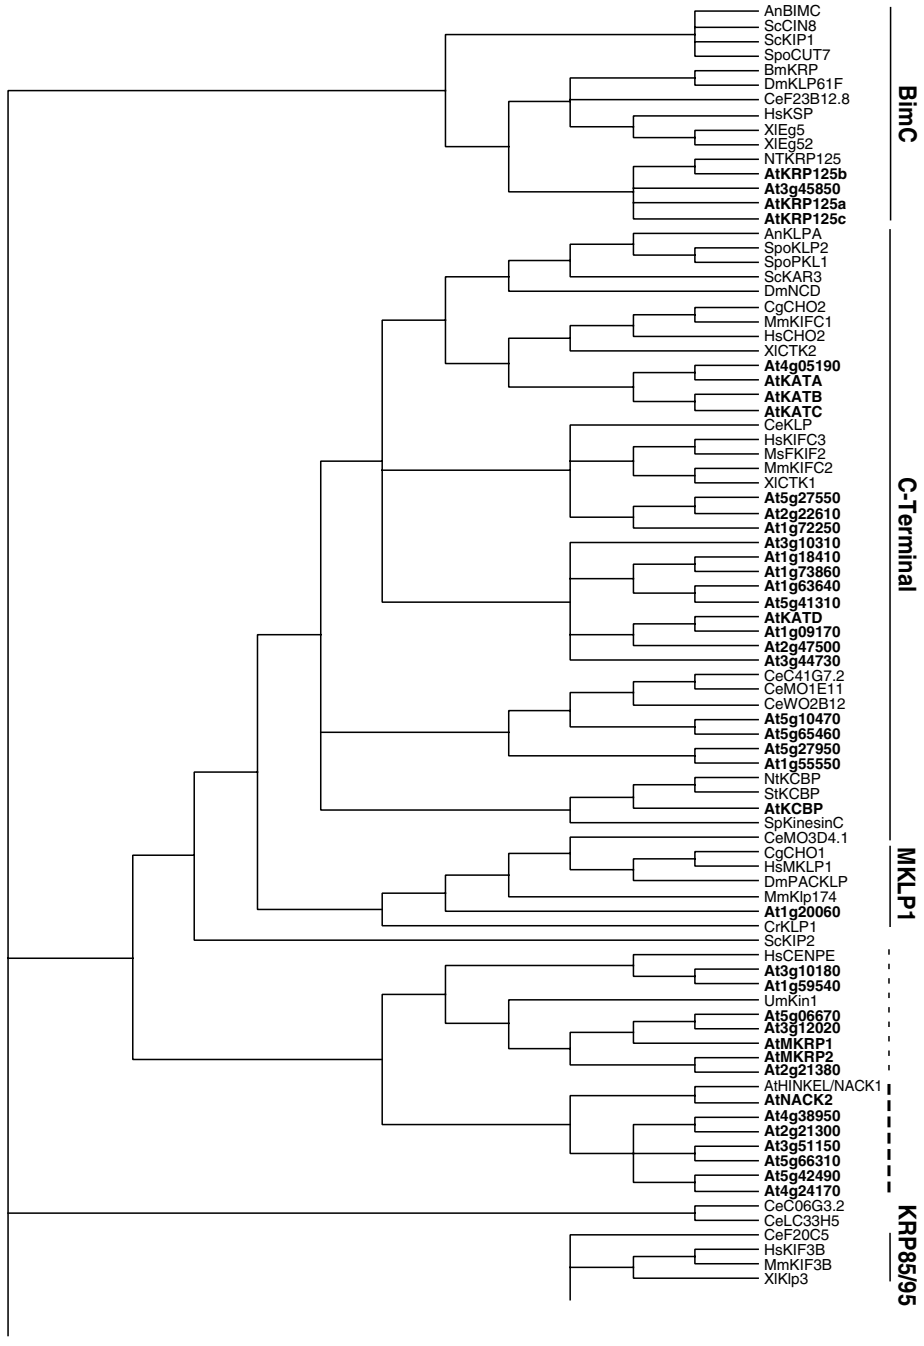

Fig. 3 (*Continued on page 476*)

expected to function in cytokinesis. Three Arabidopsis kinesins form a subgroup separate from any other kinesin, but share a branch with CeLF22F4 and DmNOD (Fig. 3). Eight other Arabidopsis kinesins form a subgroup separate from kinesins of any other organism. In many cases, a group of Arabidopsis kinesins forms a separate branch within the major subgroup in which they fall.

The large number of kinesins in plants is expected to control many diverse cellular processes including some plant-specific functions. There are many MT-associated processes that are unique to plants. For example, during cell division in plants, several plant-specific MT arrays such as the preprophase band and the phragmoplast are formed that are important in determining the future location of the cell wall and cell wall formation respectively. These unique processes are likely to require additional plant-specific motors. In addition, centrosomes play an important role in MT organization in animals, whereas plants have no well-defined centrosomes. Hence, MT organization and dynamics in plants may also require additional MT motors. The presence of unique organelles such as chloroplasts and MT-dependent processes such as cell wall synthesis may also warrant for additional motors. Also, cell-to-cell transport of macromolecules such as RNA and viruses through plasmodesmata may require MT-based motors. It is very likely that plant kinesins may participate in functions other than transport and MT dynamics and organization. Recently, it has been shown that two plant kinesins function as activators of a protein kinase. Since Arabidopsis does not have dyneins, some kinesins may be performing functions that are carried out by dyneins in other systems.

1.2 Dyneins

Dyneins move along MTs toward the minus ends. The motor domain in dyneins (~1000 amino acids) is much longer than kinesins (~340 amino acids) and does not share sequence similarity with the kinesin motor domain. Cytoplasmic dynein is a large multisubunit complex consisting of two heavy chains (~530 kDa each), three intermediate chains (74 kDa), and four light intermediate chains (~55 kDa). The central and C-terminal regions of dynein heavy chain, which are predicted to form globular structure, interact with MTs and contain motor activity, whereas the N-terminal region is thought to bind

Fig. 3 Phylogenetic tree of all Arabidopsis kinesins along with 113 nonplant kinesins. The tree was generated using the motor domain of kinesins, as described. Vertical dashes indicate ungrouped kinesins (light dashes – those grouped with other kinesins, bold dashes – exclusively Arabidopsis kinesins). The Arabidopsis kinesins are in bold. Kinesins from the following organisms were used: An, *Aspergillus nidulans*; Bm, *Bombyx mori*; Ce, *Caenorhabditis elegans*; Cf, *Cylindrotheca fusiformis*; Cg, *Cricetulus griseus*; Cr, *Chlamydomonas rheinhardtii;* Dd, *Dictyostelium discoideum*; Dm, *Drosophila melanogaster*; Gg, *Gallus gallus*; Hs, *Homo sapiens*; Lc, *Leishmania chagasi*; Lm, *Leishmania major;* Lp, *Loligo pealii;* Mm, *Mus musculus;* Ms, *Morone saxatilis*; Nc, *Neurospora crassa;* Nh, *Nectria haematococca*; N, *Nicotiana tabacum;* St, *Solanum tuberosum;* Rn, *Rattus norvegicus;* Sc, *Saccharomyces cerevisiae;* Sp, *Strongylocentrotus purpuratus;* Spo, *Schizosaccharomyces pombe*; Sr, *Syncephalastrum racemosum*; Um, *Ustilago maydis*; Xl, *Xenopus laevis.* (Modified from Reddy, A.S.N., Day, I.S. (2001b) Kinesins in the Arabidopsis genome: A comparative analysis among eukaryotes, *BMC Genomics* **2**, 2.1–2.13).

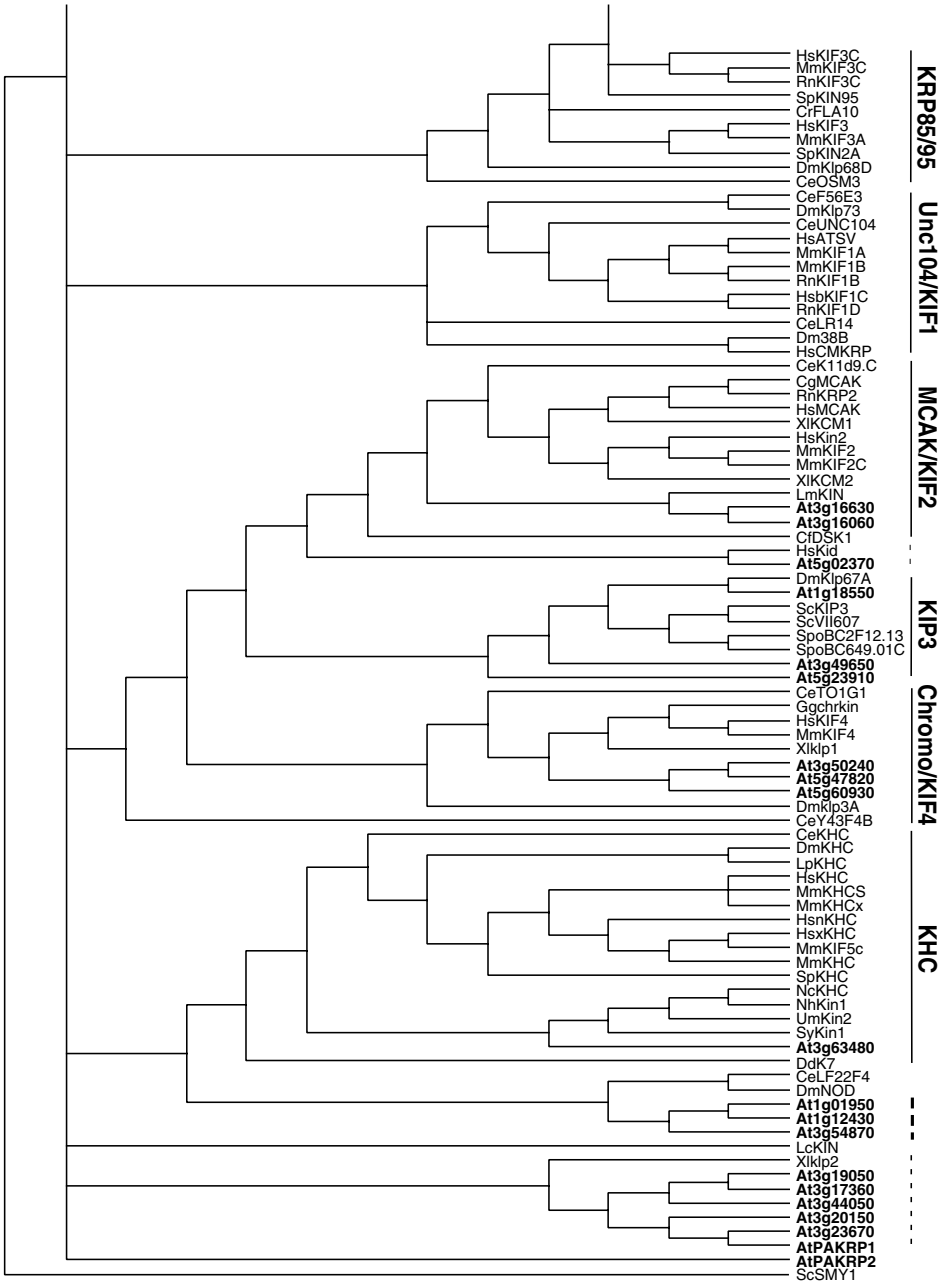

Fig. 3 (*Continued from page 474*)

cargo. The intermediate and light intermediate chains of cytoplasmic dynein associate with a protein complex called *dynactin*, which is made of 10 subunits. Although there is some immunological and biochemical data indicating the presence of dynein heavy chains in plants, sequences that are similar to dynein and dynactin subunits have not been found in the Arabidopsis genome, suggesting that they may be absent in flowering plants. The expanded family members of the kinesin superfamily may carry out the functions performed by dyneins in animals. Interestingly, dynein genes appear to be present in rice and tobacco.

2 Actin-based Motors

2.1 Myosins

Myosins, a diverse group of actin-based molecular motors, perform a broad array of cellular functions. A large number of myosins have been described in many eukaryotes. Most of these are identified on the basis of sequence similarity with the myosin motor domain. All myosin heavy chains have three common domains: a highly conserved motor domain (~850 amino acids) located at the amino-terminus in almost all myosins, which is followed by a neck region that binds to calmodulin or calmodulin-related proteins, and a C-terminal tail domain. The calmodulin-binding domain ''IQ motif'' in these myosins has a consensus sequence ''IQXXXRGXXXR'' (I, isoleucine; Q, glutamine; R, arginine; G, glycine). This motif is present in one to seven repeats, depending on the type of myosin. The only myosin that does not contain an ''IQ motif'' is myosin XIV. The tail region of different myosins varies considerably in length and structure. The tail is characteristic to each myosin with interesting domains that are also found in nonmotor proteins. The number of myosins in an organism varies among organisms. However, not all types of myosins have been identified in a single organism.

Although there is compelling indirect evidence for the role of actin and actin-based motors in various transport processes in plants, little is known about specific plant myosins that perform these functions. Myosins have been identified in plants both biochemically and at the molecular level. Immunological detection of myosins using animal myosin antibodies identified proteins of various sizes from different plants. Immunofluorescence studies localized myosin to the surface of organelles, and the vegetative nuclei and generative cells in pollen grains and tubes, to the active streaming lanes and cortical surface in pollen tubes and, more recently, to plasmodesmata in root tissues. Motility assays and ATPase assays using myosin-like proteins isolated from plants have also demonstrated the presence of myosins in plants. Using PCR-based approaches, a few myosins have been cloned from Arabidopsis and other plants.

A 170-kDa myosin has been purified from lily pollen and the antibodies against this myosin stained particles of various sizes and the apical cytoplasm of lily and tobacco pollen tubes, suggesting that several myosins are likely to be present in pollen tubes. The 170-kDa and 175-kDa myosins that translocate F-actin at a velocity of about 9 μm/s and 3 to 4μm-s respectively were found to be associated with calmodulin. In *in vitro* motility assays, the characean myosin translocated actin at 50 μm-s. In Arabidopsis, the expression of

several myosins in a given cell type implies that actin-based motors are involved in a wide range of cellular functions.

By analyzing the Arabidopsis genome sequence with the conserved motor domain of myosins, a total of 17 myosins were identified in Arabidopsis. Similar analysis in rice indicates that there are at least 14 myosins in this organism. Table 3 lists the Arabidopsis myosins by names as given in the phylogenetic tree. In comparison, *S. cerevisiae, S. pombe, C. elegans, Drosophila melanogaster* and *H. sapiens* have 5, 5, 17, 13, and 40 myosins respectively. Five of the 17 Arabidopsis myosins have been reported in the literature. All Arabidopsis myosins have three to six putative calmodulin-binding ''IQ'' motifs (Fig. 4). The IQ domains usually follow right after the motor domain, but are separated slightly from the motor domain in At XID, At XI-I, and At XIK. There are three or four IQ domains in Class VIII myosins and five or six in Class XI, except for At XIK, which has only four (Fig. 4). There are coiled-coil domains in all the myosins that differ in length and number. They often follow directly after the IQ domains, but, in some cases, there is intervening sequence. On the basis of the presence of the coiled-coil domains, it is likely that the Arabidopsis myosins either form dimers or interact with other proteins. The Class XI myosins are much longer than the Class VIII myosins with the difference being in the length of the C-terminal region following the conserved domains found in myosins. Myosins containing IQ domains are typically calmodulin-sensitive. However, the interaction with, or regulation by, calmodulin has not yet been demonstrated for Arabidopsis myosins. The information on myosin light chains is limited in plants. Calmodulin associates with two myosins from lily pollen and regulates their motor activity. Besides the motor, IQ, and coiled-coil domains, several other domains have been identified in myosins from classes other than the plant classes VIII and XI. These include SH3 domains (Src homology 3 domains), ankyrin repeats, MYTH4 (domain of unknown function found in a few classes of myosins), zinc-binding domain, plecstrin homology, FERM/talin (band 4.1/ezrin/radixin/moesin), GPA-rich domains, and a protein kinase domain. Plant myosins do not have any of these other domains.

2.1.2 Phylogenetic Analysis

Phylogenetic analysis using the conserved motor domain grouped all known myosins into 18 distinct classes. Phylogenetic analysis of the Arabidopsis myosins motor domain with nonplant and plant myosins revealed that all the Arabidopsis myosins and other plant myosins fall into only two groups, Class VIII and Class XI (Fig. 5). Four Arabidopsis myosins are in Class VIII and 13 in Class XI. These groups contain exclusively plant or algal myosins with no animal or fungal myosins, suggesting that plants have a unique set of myosins (Fig. 5). The motor domain in all cases is in the N-terminal region (Fig. 4). The motor domain starts at about 50 to 55 residues for the Class XI myosins, while the Class VIII myosins have a longer N-terminal region prior to the motor domain (99–159 residues). An algal (*Chara corallina*) myosin, Cc ccm, does group with the plant Class XI myosins, but is on a separate branch from any other Class XI myosin (Fig. 5). A phylogenetic tree that was constructed using the full-length sequences of Arabidopsis and other plant myosins showed similar grouping of plant myosins. Among the Class XI myosins, the similarity ranges from 40 to 85% (full length) and 61 to

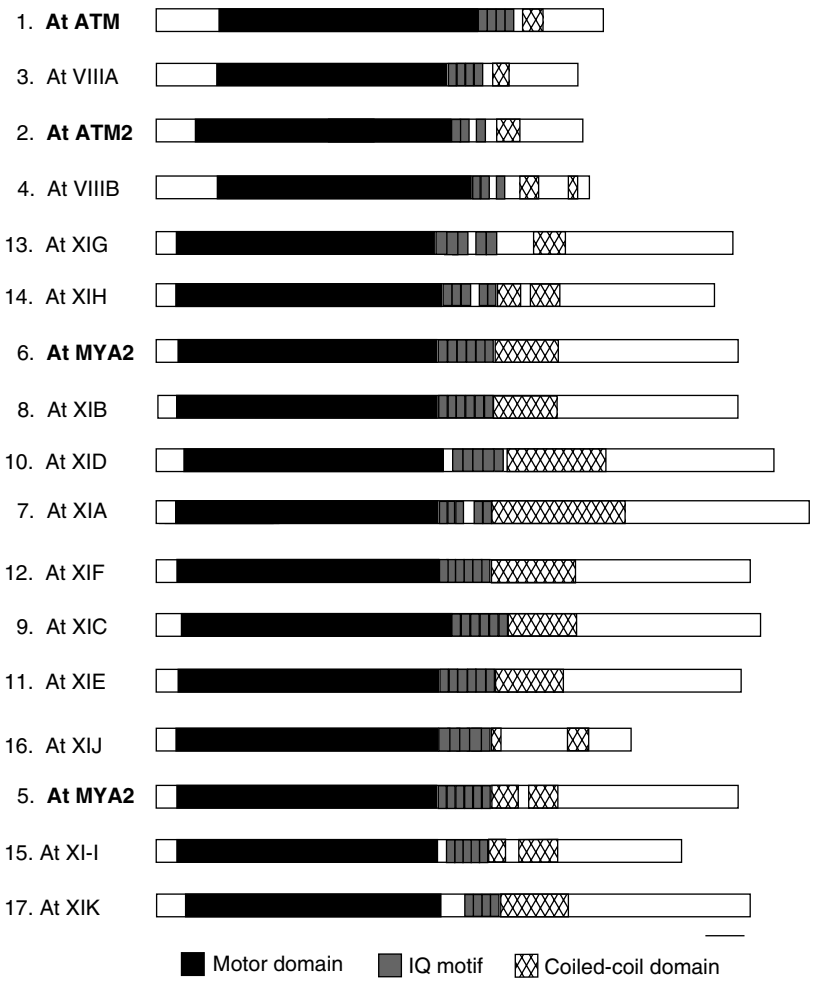

Fig. 4 Schematic diagram showing various predicted domains in Arabidopsis myosins. The Arabidopsis genome database was searched with the conserved motor domain of a myosin to identify Arabidopsis myosins. The deduced amino acid sequence of Arabidopsis myosins was analyzed for the presence of various domains. The numbers refer to the number in Table 1. The first four myosins are in Class VIII and the following 13 are in Class XI. The bar represents 100 amino acids. (Adopted from Reddy, A.S.N., Day, I.S. (2001a) Analysis of the myosins encoded in the recently completed *Arabidopsis thaliana* genome sequence, *Genome Biol.* **2**, 24.21–24.17).

91%(motor domain). The similarity between the Class VIII myosins ranges from 50 to 83% (full length) and 64 to 92% (motor domain). When Class VIII myosins are compared to Class XI myosins, the similarity only ranges from 22 to 29% (full length) and 35 to 42% (motor domain). Myosins have 131 highly conserved residues spread throughout the motor domain that define a core consensus sequence. Comparison of an alignment of Arabidopsis myosin motor domains to these conserved sequences

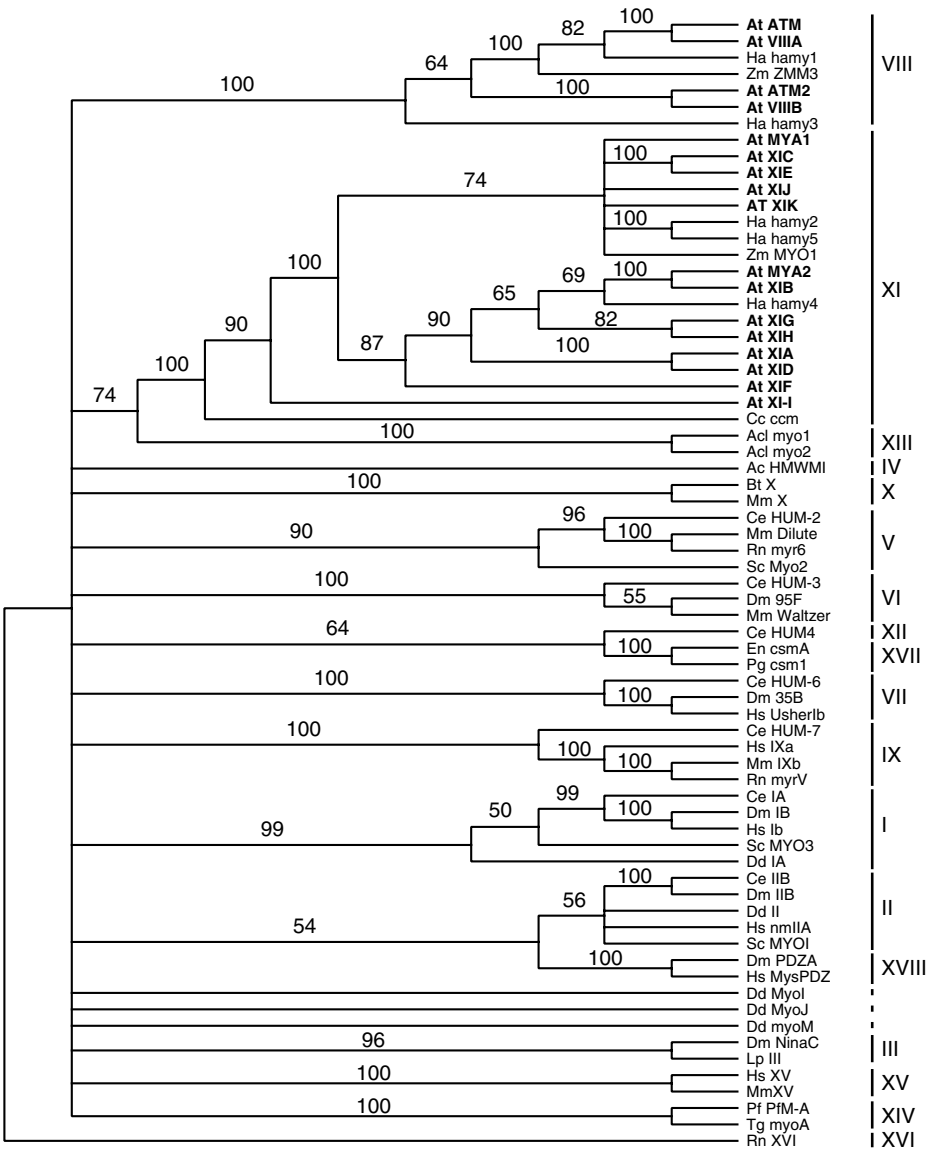

Fig. 5 Phylogenetic analysis of Arabidopsis myosins. A phylogenetic tree was generated as described earlier. The myosin groups are identified on the left in roman numerals. The Arabidopsis myosins are in bold. Myosins from the following organisms were used: Ac, *Acanthamoeba castellani;* Acl, *Acetabularia cliftoni*; Cc, *Chara corallina,* Ha, *Helianthus annuus;* Zm, *Zea mays;* Bt, *Bos taurus*; Mm, *Mus musculus;* Ce, *Caenorhabditis elegans;* Dm, *Drosophila melanogaster;* Rn, *Rattus norvegicus*; Sc, *Saccharomyces cerevisiae;* Hs, *Homo sapiens*; Dd, *Dictyostelium discoideum*; Lp, *Limulus polyphemus*; En, *Emericella nidulans*; Pg, *Pyricularia grisea*; Pf, *Plasmodium falciparum*; and Tg, *Toxoplasma gondii*. The number at the branches indicates the number of times the dichotomy was supported out of 100 bootstrap tries.

shows a great deal of conservation among them, suggesting that they are capable of motor function.

3 Cellular Roles of Motors

3.1 Cell Division

Although many of the dynamic processes of cell division such as formation of the spindle, congression of chromosomes at the equatorial region, and migration of chromatids during cell division are common to both animals and plants, there are significant differences between plant and animal cell division. For example, the dividing plant cells organize their cytoskeletal elements into unique structures that are not found in nonplant systems. Just prior to prophase, plant cortical MTs rearrange to form a band of MTs called the *preprophase band* (PPB), which accurately predicts the future location of the cell plate. Another distinctive feature of plant mitosis is the formation of a bipolar spindle in the absence of centrosomes. The structures involved in the organization of MTs are the centrosomes in animal cells and the spindle pole body (SPB) in fungal cells, which are lacking in plant cells. Finally, cytokinesis, the process that produces two daughter cells following the completion of nuclear division, in plants is accomplished quite differently from plants. Cytokinesis in plant cells occurs via the formation of a polysaccharide cell plate, which expands from the center to the periphery. Phragmoplast, a structure composed of two disks of parallel MTs, with their plus ends toward the equatorial zone, and actin filaments is involved in cell-plate formation. Vesicles carrying the cell plate materials are transported to the equatorial zone of the phragmoplast. The association of vesicles with phragmoplast MTs indicates that MT-based motors are likely to be involved in transporting the vesicles to the cell plate. The fusion of vesicles in the cell plate is mediated by phragmoplastin, a dynamin homolog, in plants. The plant spindle, which is formed in the absence of a well-defined centrosome, and several unique plant-specific MT arrays such as the preprophase band and the phragmoplast suggest that plants are likely to contain novel kinesins that are not present in animal cells.

In animals, six subfamilies of kinesins have been shown to be involved in some aspect of cell division. Several recent reports on kinesins expression and immuunolocalization indicate that at least nine plant kinesins (Kat A, KatB/C, TKRP125, AtKCBP, AtPAKRP1, AtPAKRP1L, AtPAKRP2, DcKRP120-2, HINKEL/AtNACK1, AtNACK2/TES) that belong to different families have a mitotic function. Some kinesins are expressed in a cell cycle–dependent manner. TKRP125, a member of BimC subfamily and NCAK from tobacco and two kinesins from Arabidopsis (KCBP, KatB/C) show a high level of expression in M-phase of the cell cycle. DcKRP120-1 and DcKRP120-2 are not detectable in nondividing cells. TKRP125 localizes to the cortical MTs in the S-phase, along MTs of PPB and perinuclear MTs in prophase, the equatorial plane of spindle MTs in metaphase and anaphase, and the phragmoplast MTs in telophase and cytokinesis. A carrot homolog of TKRP125 (DcKRP120-1) also localizes to the cortical MTs, the preprophase band, spindle, and the phragmoplast. Another member of BimC subfamily (DcKRP120-2) stained the spindle and phragmoplast, predominantly in the midline of the phragmoplast where plus ends of the MTs overlap. AtPAKRP1, a

nonmember of BimC, which resembles an ungrouped Xklp2 from Xenopus, also localizes to the midline of the phragmoplast. KatA, a C-terminal motor, localizes near the midzone at metaphase and anaphase and the phragmoplast in Arabidopsis and tobacco BY-2 suspension cells. Anti-KCBP antibodies stain the preprophase band, the spindle, and the phragmoplast. The KCBP antibody did not stain the cell plate region of the phragmoplast, but MT bundles on either side of the cell plate are strongly labeled (Fig. 6). Localization of KCBP in *Haemanthus* also showed localization to mitotic MTs arrays. In *Haemanthus,* anti-KCBP staining is seen almost exclusively at the spindle poles in late anaphase. The assembly of the acentriolar spindle in plants may involve convergence of MT minus ends leading to the formation of spindle poles. The fact that KCBP is a minus-end-directed motor and localizes to the spindle poles suggests that it may be involved in acentriolar spindle formation in plants. Between early and late anaphase, the localization of KCBP shifts toward the spindle pole, supporting a role for KCBP in the formation of a converging bipolar spindle. Localization of minus-end (KatA and KCBP) and plus-end (TKRP125) motors in spindle suggests their involvement in counterbalancing forces generated by plus- and minus-end motors to stabilize the spindle. Constitutive activation of KCBP during late prophase caused premature breakdown of nuclear envelope and arrest of cells at prometaphase, whereas activation of KCBP at late metaphase or anaphase did not affect the progression of anaphase, but caused aberrant phragmoplasts formation and delayed cytokinesis. This study suggests that KCBP is differentially active during the various phases of cell division. Its activity is downregulated

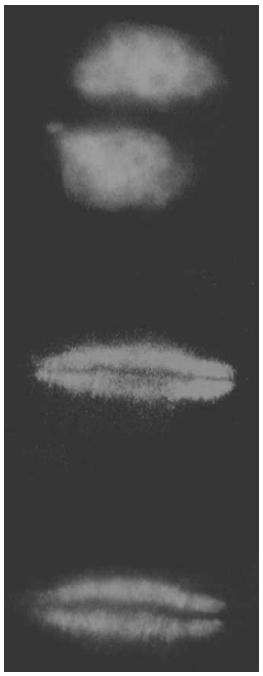

Fig. 6 Triple localization of nucleus, MTs, and KCBP in a cytokinetic cell of tobacco. Nuclei stained with DAPI (DAPI), MTs (MT) are localized with a monoclonal antibody to β-tubulin and KCBP (KCBP) was localized with affinity-purified anti-KCBP antibody. Secondary antibodies conjugated to FITC and Cy3 were used to detect MTs and KCBP respectively. (From Bowser, J., Reddy, A.S. (1997) Localization of a kinesin-like calmodulin-binding protein in dividing cells of Arabidopsis and tobacco, *Plant J.* **12**, 1429–1437).

in metaphase and telophase and upregulated in anaphase most likely by changes in cytosolic calcium level. Colocalization of some of the kinesins with mitotic MT arrays suggests that they may have a role in forming these arrays by bundling MTs. The motor domain of KCBP has been shown to bundle MTs.

Numerous forces are at play in the development, maintenance, and function of the phragmoplast. Golgi-derived vesicles are transported to the forming cell plate where the plus ends of phragmoplast MTs interdigitate. It is likely that MT motors are involved in forming the phragmoplast and powering the movement of the vesicles along the MTs. Seven plant kinesins (Kat A, TKRP125, AtKCBP, AtPAKRP1, AtPAKRP2, DcKRP120-2, HINKEL/AtNACK1) including plus- and minus-end motors and some plant-specific kinesins are associated with the phragmoplast and so are expected to function in cytokinesis. The localization patterns with various kinesins differed considerably. Immunolocalization studies as well as phragmoplast MT gliding assay in the presence of TKRP antibodies indicates its involvement in the organization of MT arrays especially in phragmoplast function. The polarity of MTs and microfilaments in the phragmoplast indicates that plus-end motors are likely to be involved in the transport of vesicles to the cell plate. Of the eight kinesins that localize to the phragmoplast, six are N-terminal motors (TKRP125, PAKRP1, PAKRP1L, DcKRP120-2, PAKRP2, HIK/NCAK) and two are C-terminal (KatA and KCBP). TKRP125 is a plus-end motor, and the other four N-terminal kinesins are likely plus-end motors. One or more of these are likely to be involved in vesicle transport to the cell plate. The punctate-staining pattern of PAKRP2 and its association with vesicles suggest that it is involved in transporting vesicles to the cell plate. It is unlikely that KCBP and KatA play a role in vesicle transport to the cell plate as these are known to be minus-end motors and the MTs are oriented with their plus ends facing the cell plate. The possible functions of minus-end motors are organization/stabilization of phragmoplast and/or recycling of Golgi vesicle membranes from the expanding cell plate. Functional analysis of TKRP125 indicates its role in cross-linking and sliding of antiparallel MTs in the phragmoplast. Immunofluorescence with AtPAKRP1 and AtPAKRP1L antibodies showed staining of interzonal MTs at late anaphase and later on its localization is restricted to the plus ends of interdigitating MTs in the phragmoplast. Functional studies with this kinesin indicate its involvement in maintaining the integrity of phragmoplast MTs. In order for the growth of the phragmoplast to be achieved, a rapid turnover of phragmoplast MTs must occur. The expansion of the phragmoplast from the center to the periphery involves disassembly of the MTs inside and assembly of MTs at the outside. Blocking of disassembly in the center by MT-stabilizing drugs causes cessation of phragmoplast expansion and formation of incomplete cell walls. Phragmoplast-associated kinesins may play a role in the MT assembly and disassembly associated with its growth. The loss of MTs from the center of the phragmoplast as it grows does not occur in *hik* mutants, suggesting that it controls directly or indirectly the dynamics of MTs in the phragmoplast. HIK does not appear to be involved in either vesicle transport or organization of MTs in the phragmoplast. Studies with tobacco NCAK1, a homolog of HINKEL, showed its localization to the equatorial zone of the phragmoplast, but not in the inner regions

of the phragmoplast where the cell plate matures. It appears that NCAK through a protein kinase, NPK1, regulates depolymerization of MTs in the center of the phragmoplast as it expands.

There is some evidence of the presence of a myosin in the phragmoplast, suggesting that actin-based motors may also be involved in the transport of vesicles on the phragmoplast. During cell division, the anti-Class VIII myosin staining remains confined to the transverse cell walls and is strongest in the newly formed cell wall. Immunogold electron microscopy showed labeling of Class VIII myosin associated with the plasma membrane and plasmodesmata. These studies suggest that Class VIII myosins may be involved in new cell wall formation and transport in the plasmodesmata.

3.2 Cell Polarity and Morphogenesis

Both actin and MT cytoskeleton have been implicated in cell polarity and morphogenesis. The first indication that a kinesin might play a role in morphogenesis came from studies with the *zwichel* mutant. In wild-type Arabidopsis, trichomes are unicellular with a stalk and three branches. In *zwichel* (*zwi*), mutants' trichomes are abnormal with a short stalk and one or two branches, depending on the severity of the allele (Fig. 7). Cloning of *ZWICHEL* has indicated that it is a calmodulin-binding kinesin, suggesting the requirement of this motor for expansion of the stalk and branching. Using paclitaxel, a known MT stabilizer, *zwichel* mutants were induced to form similar growth points indicative of branch formation in normal trichomes. Transient stabilization of MTs could compensate for KCBP/ZWI activity, suggesting that it may be involved in stabilization of MTs. The two MT-binding sites of KCBP could be involved in stabilization or possibly a KCBP/ZWI-interacting protein(s) could be responsible for the stabilization. Several alleles of *zwi* have been characterized. All *zwi* mutants grew normally with no apparent defects in cell division, except that they contain abnormal trichomes. The lack of a phenotype in other tissues suggests that either KCBP is nonessential or another motor

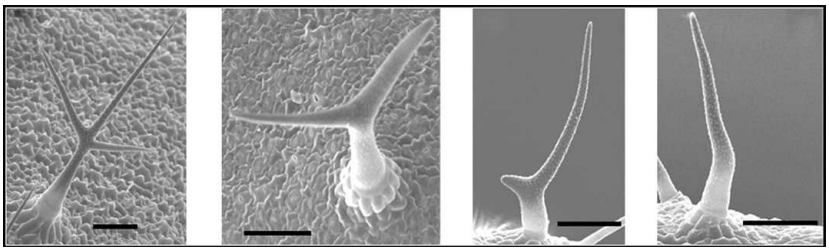

Fig. 7 Scanning electron micrographs of Arabidopsis trichomes of wild-type and *zwichel/kcbp* mutants. (a) Wild type; (b) *zwi*; (c) *zwi w2*; (d) *zwi9311 -11*. In *zwi w2,* most trichomes have two branches but the length of the second branch is varied. In the *zwi9311-11* mutant, about 40% of trichomes are unbranched and the rest have two branches. Seeds of *zwichel* mutants were kindly provided by Dr. David Oppenheimer and Dr. Martin Hülskamp. Scale bar = 100 µm (From Reddy, A.S.N., Day, I.S. (2000) The role of the cytoskeleton and a molecular motor in trichome morphogenesis, *Trends Plant Sci.* **5**, 503–505).

with overlapping functions may substitute for ZWI function in other tissues. In Arabidopsis, there are 61 kinesins including several C-terminal motors. Three extragenic suppressors (suppressor of *zwichel*-3; *suz1, suz2,* and *suz3*) that rescued trichome branch number defect in a *zwichel* mutant have been isolated. All three suppressors were found to be allele-specific, indicating direct interactions between these proteins. The *suz1 zwi-3* double mutants are male sterile due to a defect in pollen germination and pollen tube growth, suggesting a role for these genes in pollen germination and tube growth. At least four proteins (two calcium-binding proteins, a plant-specific protein kinase, and ANGUSTIFOLIA, a protein required for trichome branching) have been shown to interact with KCBP/ZWI. Inactivation of one of the myosins (*MYA2*) of myosin XI family in Arabidopsis also results in abnormal (unbranched) trichomes.

3.3 Cytoplasmic Streaming

Cytoplasmic streaming in plant cells is important in intracellular transport. The force that drives the cytoplasmic streaming appears to be dependent on actin and actin-based motors. Insight into the function of plant myosins in cytoplasmic streaming has been gained primarily by studies done with algae and pollen tubes. Characean cells exhibit a very rapid cytoplasmic streaming ($\sim$70 $\mu m\ s^{-1}$). Also, in pollen tubes, vesicles flow rapidly from the shank to the tip of the pollen tube where they fuse to support extensive tip growth of these cells. In addition to the bidirectional movement of vesicles, the generative cell and the nucleus move unidirectionally toward the tip. In *Chara,* an increase in Ca^{2+} concentration causes cytoplasmic streaming to stop. A myosin isolated from the alga *Chara corallina* was shown to be responsible for cytoplasmic streaming. The myosin was cloned and found to be a Class XI myosin related to the Arabidopsis MYA myosins. Using immunofluorescence, myosin was localized to vesicles, organelles, and generative cells and vegetative nuclei in grass pollen tubes. A myosin isolated from lily pollen has been shown to be responsible for cytoplasmic streaming in pollen tubes, and two myosins were identified in tobacco cell cultures are also thought to participate in cytoplasmic streaming. Myosin has been localized to vesicles, chloroplasts, and other organelles, indicating their involvement in transport of these organelles. The stop-and-go movements of Golgi stacks in plants also appear to be dependent on myosin. However, specific myosin(s) responsible for the movement of these organelles have not been identified. Biochemical properties and the localization data of two lily pollen myosins (175 kDa and 170 kDa) suggest that these myosins are at least partially responsible for cytoplasmic streaming, organelle transport, and calcium sensitivity of cytoplasmic streaming. It has been shown that the directional movement of mitochondria is dependent on F-Actin and myosin system. Unlike in animals, the movement of peroxisomes in plants is actin-based and actin polymerization appears to drive the movement of these organelles.

3.4 Microtubule Dynamics and Organization

Microtubules are highly dynamic structures with a half-life of an individual MT of about 10 min. Drugs that disrupt the dynamics of MTs have been shown to

severely hamper the MT-dependent process. Treatment of dividing cells with colchicine leads to disappearance of the mitotic spindle, suggesting that MTs in the spindle undergo continuous polymerization and depolymerization. Taxol, in contrast to colchicine, bind to MTs and stabilizes them. Addition of taxol to dividing cells leads to arrest of dividing cells in mitosis. The dynamics of the MT cytoskeleton during cell division in plant cells have been studied extensively. The rapid turnover of plant MTs suggests that the transition between MT arrays and change in orientations may involve depolymerization/repolymerization of MTs and/or movement of MTs. The dynamic instability of MTs is important for their normal function. For example, stabilization of MTs in elongating root hairs causes loss of growth directionality and promotes branching. The MTs of the phragmoplast have a t1/2 of 60 s. However, the mechanisms that regulate the formation and dynamic instability of MT arrays in plants are not understood. Several aspects of MT dynamics such as cross-linking, zippering, bundling, sliding, and stability of MTs is regulated by motor proteins. KCBP like Ncd in *Drosophila* can cross-link and zipper MTs to focus MTs to form spindle poles. Two distinct MT-binding sites and minus-motor activity enable these proteins to perform such a function. In addition, C-terminal motors have been shown to bundle MTs. Some motors are implicated in polymerization and depolymerization of cytoskeletal elements. There is at least one example where a kinesin has no motor activity, but controls MT dynamics. Plant kinesins such as NCAK1 appear to be involved in MT dynamics. Hence, the paradigm that motors bind cargo and move along cytoskeletal tracks may not explain the functions of all the motors.

3.5 Intercellular Transport

Plant cells are connected through plasmodesmata to form a continuous symplastic network. Recent studies show that macromolecules such as RNA and protein move from cell to cell through plasmodesmata. Cytoskeleton and molecular motors have been implicated in this regulated transport of macromolecules through plasmodesmata. The movement protein of viruses, which enables the movement of viruses from cell to cell colocalizes to MTs, suggesting a role for cytoskeleton and possibly molecular motors in the transport of protein from cell to cell through plasmodesmata. These studies hint at an interesting possibility that motors may play a role in transporting macromolecules from cell to cell and influence cell-to-cell communication. Immunolocalization studies have also detected myosin associated with plasmodesmata. A recent study using an antibody to a cloned Class VIII Arabidopsis myosin ATM1 (At ATM) localized this myosin to the plasmodesmata and the plasma membrane regions involved in the assembly of new cell walls. Earlier work suggested that actin was involved in regulation of plasmodesmal transport. Other studies using antibodies to animal myosins in root tissues of *Allium cepa, Zea mays*, and *Hordeum vulagare* have also indicated the presence of myosin in the plasmodesmata.

3.6 Other Functions

It appears that the certain plant motors may perform unexpected novel functions.

For example, two plant kinesins (NCAK1 and NCAK2) have been shown interact with NPK1, a MAP kinase–kinase–kinase, and stimulate its activity. Motors in plants may also be involved in regulating cell polarity, development, and differentiation by transporting the proteins or mRNA to localized regions within the cell. There is substantial indirect evidence indicating that asymmetric localization of mRNA (e.g ASH1 mRNA in yeast), protein (e.g. calmodulin in Drosophila photoreceptors, a MAPKKK in tobacco BY2 cells), and RNA/protein complexes in some eukaryotic cells is dependent on cytoskeletal motors.

4 Regulation of Motors

Although a large number of kinesins have been characterized from diverse organisms (www.blocks.fhcrc.org/~kinesin/), the mechanism that regulate the activity/function of MT-dependent motors is limited both in plants and animals.

4.1 Calcium/Calmodulin

Calcium is a key messenger in transducing many hormonal and environmental signals in plants. Calmodulin, a ubiquitous calcium-binding protein in eukaryotes, is highly conserved in eukaryotes and regulates many diverse cellular functions by modulating the activity of the proteins that interact with it. Upon binding calcium, calmodulin becomes activated via a conformational change and is able to regulate the activity of its target proteins. Cytoplasmic streaming of characean cells is regulated by the cytosolic calcium concentration. Elevated levels of calcium inhibit cytoplasmic streaming and the movement of organelles. Movement of pollen tube organelles along actin cables is inhibited by calcium, suggesting that the activity of actin-based motors is sensitive to calcium levels. The mechanisms by which calcium regulates the activity of these motors is just beginning to emerge. All myosins in Arabidopsis possess two or more putative calmodulin-binding motifs, suggesting that myosins in plants are likely to be regulated by calmodulin in response to changes in intracellular calcium. Two myosin heavy chains (170 and 175 kDa) in plants associate with calmodulin, indicating that calmodulin serves as a light chain for these myosins. Calcium inhibits the myosin motor activity as well as myosin-activated ATPase activity in plants. The inhibition of myosin activity in the presence of calcium appears to be due to dissociation of calmodulin from the heavy chain since calcium inhibition of motor activity can be restored by exogenous addition of calmodulin. The gene encoding 175-kDa myosin has been cloned. Sequence analysis indicates that it is a Class X1 myosin with six IQ motifs. This myosin has been shown to move processively on actin filaments.

KCBP and recently discovered kinesin C are the only kinesins among the kinesin superfamily that bind calmodulin. The binding of activated calmodulin to KCBP inhibits its interaction with MTs via the calmodulin-binding domain, resulting in the inhibition of MT-dependent ATPase activity and motility. These studies strongly suggest that the binding of calmodulin to KCBP affects MT-binding regions, resulting in inhibition of KCBP binding to MTs and dissociation of KCBP/MT complex. Crystal structure of

KCBP motor domain with its calmodulin-binding domain indicates that calmodulin binding to KCBP blocks MT-binding sites on the motor. The calmodulin effect on KCBP suggests that activated calmodulin can act as a molecular switch to down-regulate the activity of KCBP. On the basis of *in vitro* studies with KCBP, it is reasonable to speculate that spatial and temporal changes in free cytosolic calcium levels in response to signals are likely to regulate KCBP activity in the cell.

4.2 Protein Phosphorylation

The members of BimC family have a conserved ''BimC Box'' in which threonine residue is phosphorylated by cdc2-kinase during cell division. Targeting of the kinesins to spindle is regulated by phosphorylation. TKRP125, all three members of Arabidopsis TKRP-like proteins (AtKRPa, b, and c), and DcKRP120-1 and DcKRP120-2 that belong to BimC family have the conserved BimC box, suggesting that phosphorylation of these kinesins may be involved in targeting them to right cellular location. Recently, it was found that the tail region of KCBP also interacts with a protein kinase (KIPK, KCBP interacting protein kinase) in the yeast two-hybrid system. The association of KIPK with KCBP suggests regulation of KCBP or KCBP-associated proteins by phosphorylation and/or KCBP is involved in targeting KIPK to proper cellular location. The tobacco NPK1, a mitogen-activated protein kinase–kinase–kinase, NPK1, interacts with NACKs. This interaction results in activation and autophosphorylation of NPK1 and phosphorylation of NACK1. Although the significance of NACK1 phosphorylation is not known, NPK1 phosphorylation targets it to the equatorial zone of the phragmoplasts. A cyclin-dependent kinase (CDK) has been shown to interact with two Arabidopsis kinesins (KCA1 and KCA2). This interaction results in phosphorylation of kinesins, suggesting that the activity/function of these motors may be regulated by CDK.

5 Concluding Remarks

The complete sequencing of several phylogenetically diverse model organisms ranging from a unicellular eukaryote to highly complex multicellular animals and plant has allowed comparative analysis of molecular motors in eukaryotes. Plants contain a large number of motors. About 0.4% of the predicted genes in Arabidopsis encode molecular motors. The comparative analysis provides a framework for future functional studies with plant kinesins. The number of myosins in Arabidopsis is comparable to other multicellular organisms of similar genome size. However, plant myosins are unlike myosins from any other organism except algae. Nonplant myosins contain a variety of other known domains that are lacking in plants. Furthermore, Arabidopsis has a surprisingly large number of kinesins among the completed eukaryotic genomes. The role of molecular motors in many plant cellular processes is beginning to be unraveled. Although the functions of most of the plant motors remains to be determined, phylogenetic analysis and known domains in these proteins are providing clues to their function, which can be tested empirically. Many Arabidopsis kinesins do not fall into any known subfamilies of kinesins, and several Arabidopsis kinesins are not

present in other organisms and are likely to represent new plant-specific subfamilies. Analysis of expression of each motor and cellular localization using reporter fusions coupled with studies using the loss-of-function and gain-of-function mutants should help understand the functions of these motors. Identification of the proteins that are associated with motors is also important to our understanding of their roles in plants. Knockout mutants for almost all Arabidopsis motors are already available from SIGnAL (http://signal.salk.edu/). Because of the large number of motors and likely functional redundancy or overlap with other motors, it will be necessary to create not only single mutants but also double or triple mutants. Analysis of the function and regulation of plant motors will be an exciting area of research in plant cell biology and is bound to throw many surprises.

Acknowledgment

I thank members of my laboratory and all my collaborators for their contributions. I wish to thank Irene Day for preparing the figure and critically reading the manuscript. Research on motors in my laboratory is supported by grants from the National Science Foundation (MCB-9630782 and MCB-0079938).

Keywords

CNS
Central nervous system.

Dendrite
Postsynaptic neuronal processes branching from cell soma that receive information from presynaptic cells.

Expression Profile
Relative abundances of multiple RNAs.

Postsynaptic
Cell that receives a signal from a neuron.

Presynaptic
Cell that sends a signal to another neuron.

Proteomics
Analysis of multiple proteins simultaneously.

aRNA
Amplified antisense RNA.

RT-PCR
Reverse-transcribed PCR.

qRT-PCR
Quantitative reverse-transcribed PCR.

Synapse
Connection point between a presynaptic and postsynaptic neuron.

The brain is composed of hundreds of thousands of cell types, each making thousands of connections to other cells in order to communicate and to facilitate proper interactive functioning. One of the ways that cells respond to and propagate signals is to change the abundances of various signaling molecules within the cell. These molecules include RNA and proteins, which, through their unique abundances and degree of activation transmit accurate messages to responsive cells. To understand these changes, evaluation of molecular pathways in single cells is required. With the development of single-cell molecular biological analysis techniques, changes in RNA and protein abundances can be monitored. Using methods such as, aRNA amplification, qRT-PCR, IDAT and protein arrays it is possible to obtain these measurements. Such anatomical specificity has the potential to revolutionize molecular research by simplifying the complexities of a multicellular pathway to an experimentally approachable system.

1 Importance of Single-cell Molecular Experiments

With a system in charge of complex tasks like memory, senses, mood, and development, it is not surprising that the cellular composition of the brain is equally complex. Neurons and glia are the two dominant classes of cells in the central nervous system (CNS). Neurons are thought to be at the heart of all cell–cell communication; yet, recent data has highlighted the importance of glial cells in modulating neuronal function. The variety of neuronal and glial cell types and their connections allows for the distribution and integration of information involved in everyday activities. Over the last century, it has become clear that an understanding of the complexities of CNS functioning requires not only utilization of systems science but also the reductionist approach of characterization of the individual components of the system. The development of single-cell molecular techniques has enabled researchers to begin to differentiate between not only the activities of the different regions of the brain but also the different types of cells that make up each of these regions. It is estimated that there are hundreds of thousands of cell types in the brain, each expressing tens of thousands of mRNAs in differing abundances. These differences in the abundances of RNAs as well as selective gene expression in each cell enables the complexity whereby so few chemicals in the brain produce diverse cell-specific responses.

Prior to single-cell experimental procedures, experiments used whole brain or regional sections of cells to try to elucidate the molecular changes in response to outside stimuli. Whether such stimuli originate as a result of disease, behavior, or pharmacological stimulation, quantitation of the resulting cellular responses at the molecular level enables researchers to begin to decipher what underlies the subsequent response. Since an individual neuron can have thousands of connections (synapses) with other cells that feed and distribute information, it is likely that there are differences in expressed gene phenotypes in each cell depending upon the types and quantity of these connections.

Importantly, diseases such as Alzheimer's do not necessarily affect every cell in an affected brain region. Therefore, if a group of cells were evaluated to investigate the cellular response to a stimulus, it would be hard to separate the nonresponsive cells' molecular milieu from that of the responsive cells. Single-cell molecular methods now allow researchers to separate and study target genes or whole expression pathways in individual cells so that specific cellular phenotypes can be described.

2 Isolation Techniques

After determining and marking which cells are of interest in an experiment, single cells can be collected either from fixed-tissue samples or from live cells in culture.

2.1 Microaspiration of Live Cells

Live cells in primary cell culture, continuous cell culture, or slice culture can provide a source for single-cell RNA and protein analysis. These studies require the precise removal and collection of the cytoplasmic contents of individual cells. This precision is afforded through the use of electrophysiological sampling procedures, namely whole cell patch pipette harvesting (Fig. 1). In this procedure, a thin capillary tube is drawn to a very fine tip and used to impale a cell. The cytoplasmic contents (RNA and protein) can then be aspirated into the pipette and transferred to a microcentrifuge tube for further manipulation and analysis. This technique further allows for collection of electrophysiological data from the cell to be harvested. The marrying of analyses, electrophysiological and molecular, permits a detailed phenotypic portrait of the cell to be obtained. The analysis of the mRNA complement of the isolated cellular material requires amplification (discussed later in this chapter) of the RNA signal; consequently, the mRNA must initially be converted into cDNA. This is accomplished by reverse transcriptase and can be initiated either in the microcentrifuge tube or directly in the patch pipette. Very fine manipulations are possible in this approach, allowing not only for single or multiple cell collection but also for isolation of cellular subregions such as dendrites, axons, or cell bodies. Although this is a time-intensive technique, the fine control allows for very accurate analysis of the RNA content of single cells.

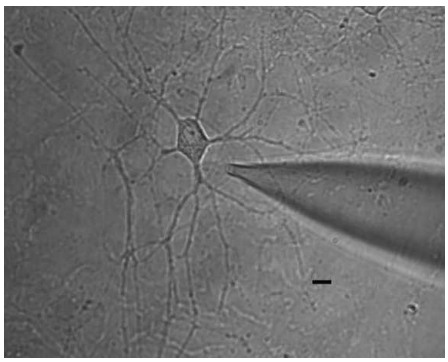

Fig. 1 Harvesting of a neuronal cell soma with a patch pipette – The manual harvesting of the cytoplasmic contents of a single rat hippocampal neuron in culture is shown. In this phase contrast image, the patch pipette used to harvest the cytoplasmic contents is in the foreground and the vast dendritic arborization associated with this neuron is clear. Aspiration through the patch pipette affords the negative pressure necessary to bring the cellular contents into the pipette. The black scale bar below the pipette corresponds to ~10 γm.

2.2 Microaspiration of Fixed Cells

Oftentimes it is difficult to obtain live cells from a particular brain region or from a particular species (e.g. human). Fixed-tissue sections offer the advantage of being able to examine cellular processes in many different cell types from essentially any organism. Fixation usually involves either chemical cross linking of proteins and nucleic acids or intracellular precipitation of these entities to preserve their localization and abundances during tissue processing. When collecting single cells from fixed-tissue sections, there are two commonly used techniques. The first technique is microaspiration, where micromanipulators and a microcontrolled vacuum are to remove the cellular constituents of the single cell. Often, the fixation protocol will dictate the success of this harvesting procedure. If the goal of these studies is to determine the RNA composition of an individual fixed cell, then as a prelude to nucleic acid amplification, cDNA synthesis is often performed *in situ* prior to microdissection of the identified cell.

2.3 Laser Capture Microdissection

The second method for single-cell collection is laser capture microdissection (LCM). This procedure uses an infrared laser beam to melt a transparent polymer transfer film (ethylene vinyl acetate polymer) so that it permeates the individual microscopically imaged cell. When the film is lifted, the desired cell is detached from all other surrounding cells and connective tissues. The film adheres to a transparent cap, which can subsequently be placed in a vial to perform any further desired manipulations. Although a laser is used, the energy emitted by the laser is thought to not interfere with the morphology of or the chemical composition of the isolated cell. It is important to note that issues of surrounding cellular contamination and method of fixation will impact the utility of LCM. With these caveats in mind, this method promises a fully animated, fast way to obtain a single cell sample, or many cells of a similar type depending upon the goals of the experiment. Additional newer methods for laser dissection have been developed that do not rely upon film transfer. These procedures use a low-power laser to separate the cell of interest from surrounding tissue, and a higher-powered beam transfers the cell to a vial. This LCM approach offers an advantage over the cap collection methodology of limiting the amount of surrounding-cell contamination.

3 mRNA Profiling

3.1 *In situ* Hybridization

There are two basic questions that can be asked when evaluating mRNA in single-cell experiments. The first is ''is a mRNA present within the cell'' and the second is ''what is the quantity of the RNA.'' Table 1 summarizes the benefits and disadvantages of each mRNA profiling method. The second column refers to the quantitative nature of the amplification of the technique. The third column addresses whether the method measures the presence of individual mRNAs or the mRNA population. The fourth column refers to the amount of sample required for quantification. Lastly, the final column suggests how difficult the procedure is

Tab. 1 mRNA profiling.

	Quantitative	*Individual/population*	*Sample size*	*Simplicity*
In situ hybridization	No	Individual	Small	
RT-PCR	Semi	Individual	Small	
qRT-PCR	Semi	Individual	Small	
aRNA amplification	Yes	Population	Small	
Microarray	Yes	Population	Large	Advanced

to use. To evaluate the existence or coexistence of mRNAs in a single cell, a commonly employed technique is *in situ* hybridization (ISH). This technique uses labeled complementary RNA probes to bind to the RNA of interest. After permeabilizing the cell membrane, the probe is hybridized to the target RNA and, in turn, the RNA tag (Fluorescence, radioactivity, DAB, etc.) is visualized to determine the cellular location of the RNA. By using more than one type of fluorescence label, it is possible to determine the colocalization of multiple RNAs in a single cell. This technique can be used to localize RNAs to subregions of cells and, more recently, as a verification of other mRNA profiling techniques. However, ISH is quite difficult to quantitate; consequently, its use as a confirmation of RNA abundances determined by other procedures such as microarray analysis is limited. ISH is quite useful in differentiating between decreased mRNA levels due to decreased cell numbers versus decreased mRNA levels.

3.2 RT-PCR

Once a single cell has been harvested, there are many methods available to evaluate differences in mRNA levels due to variables such as disease or cellular stimulation. Since the quantity of mRNA in a single neuron or glia is quite small, often the first step in the evaluation process is amplifying the mRNA signal. This can be done by using a technique called *reverse-transcription polymerase chain reaction* (RT-PCR). After the mRNA is harvested from a cell, the first step in the amplification process is to anneal a specific primer to the mRNA of interest. Upon annealing, the reverse transcriptase will bind and, in the presence of dNTPs, create a complementary strand to the mRNA (cDNA). Next, the original mRNA is removed and a second primer binds to the cDNA strand to direct binding of a DNA polymerase that creates a copy of the first cDNA strand. This double-stranded cDNA is then used as a template for the iterative action of TAQ polymerase and the primers in the PCR amplification procedure. Such amplification is necessary since a large amount of the product is required for later quantitative analysis. During each round of PCR, the amount of DNA doubles, so in an average PCR reaction (27 rounds of amplification), the theoretical amplification yield is approximately 2^{27} or 10^8 cDNA copies (amplicons). Although this technique is used to quantify the mRNA abundance from a single cell, the PCR amplification is not linear and can lead to a skewing of amplicon abundance thereby producing aberrant results. mRNAs in the initial RNA pool that are present in lower

abundances are often not amplified to the same degree as more abundant mRNAs in the reaction mixture. This misrepresentative amplification is multiplied as the PCR amplification occurs. Also, secondary structure in the RNA or cDNA may lead to the TAQ polymerases falling off the strand, producing cDNAs that are not long enough to contain the second primer binding site, resulting in erroneously low quantitative results.

3.3 qRT-PCR

A convenient method that provides rapid RNA abundance measurements is quantitative RT-PCR (qRT-PCR) and is usually used to probe individual RNAs as opposed to the population of RNAs. Using the reverse-transcription method described above, cDNA is made from the original mRNA. During the PCR step, a quenched fluorescent probe is added, which binds selectively to the cDNA. When the polymerase moves along the strand, the quenching region of the probe is cleaved and the probe fluoresces. Using a spectrofluorimeter, the level of fluorescence is measured after each round of PCR. The number of rounds required to reach a threshold point can be compared between target RNAs in the sample. Quantitative results can only be achieved through quantitation during the linear phase of amplification prior to the point of PCR saturation. The amplified products corresponding to the RNA of interest are often normalized to a housekeeping gene for further comparison purposes and to limit variability. This technique limits the need for further quantification after amplification; however, many of the nonlinear problems described for RT-PCR also apply to this method.

3.4 aRNA Amplification

A second form of quantitative amplification is antisense RNA (aRNA) amplification. As originally described, this technique makes use of the fact that mRNA has a poly-A tail by using a complementary dT primer containing the T7 promoter to begin reverse transcription on the starting mRNA. Following the production of the first strand of cDNA, the original RNA is removed and the complement second strand cDNA is created, creating a functional T7 promoter. T7 RNA polymerase is then added to transcribe multiple antisense RNA copies from the new cDNA. Given that one round of RNA amplification produces up to 10 000-fold amplification, an important aspect of this technique is that only two rounds of amplification are required to obtain $\sim 10^6$ copies of the aRNA. This limits the problems of nonlinear amplification that are apparent from 25 to 40 rounds of RT-PCR.

3.5 Microarrays

Following a quantitative amplification protocol, microarrays are often used as a way to measure the abundance of thousands of genes simultaneously. This process usually begins with a solid support, either a glass slide or nylon membrane, with multiple oligonucleotides ''printed'' or deposited onto the surface in a square grid pattern. These grids can be ''printed'' by adding one nucleotide at a time until the complete sequence is present. Similarly, the grids can be made through direct deposition of cDNAs. The amplified RNA

or cDNA, made from the aRNA, is then radioactively or fluorescently labeled and hybridized to the microarray. Any immobilized oligonucleotides or cDNAs with the complementary sequence will bind the labeled aRNAs. After hybridization occurs, either fluorescence can be measured with a spectrofluorimeter or the radioactive signal is visualized using a phosphorimager. Since the pattern of DNAs immobilized on the membrane is known, the levels of fluorescence or radioactivity represent the quantity of RNA that is bound to each particular DNA on the array. There are two main benefits of using fluorescent dyes as opposed to radiolabeling; the first is that, instead of exposing the array to a phosphor screen for up to seven days, fluorescence can be measured immediately following hybridization. The second advantage is the possibility of using multiple dyes that fluoresce with different colors allowing for competitive hybridization comparison of RNAs profiles from different samples on the same array. Radioactively labeled probes have the advantage of being more sensitive; therefore, they are better able to detect a small amount of RNA.

3.6 Experimental Examples of Profiling

There are many areas of study where the techniques of RNA profiling can be used. One is in interpreting the molecular changes associated with disease state. For example, an area of important neurological disease research is understanding the genetic, genomic, and proteomic underpinnings of schizophrenia. The hope is that by targeting the molecular deficits in affected cells, researchers may be able to create chemicals that are therapeutically effective. For example, in the prefrontal cortex (PFC) of schizophrenia patients, there is a deficit of glutamate decarboxylase (GAD) mRNA which is necessary for the synthesis of the neurotransmitter GABA. Since the PFC is a brain region involved in working memory and is known to be impaired in schizophrenic individuals, understanding the pathways leading to these deficits might uncover novel treatments of this symptom. Single-cell mRNA profiles have shown that while some GABAergic neurons had normal expression other neurons exhibited expression far below control levels. Using molecular techniques, it is possible to investigate which subset of GABAergic neurons exhibits such deficits.

Such cellular specification highlights the selectivity of vulnerable cell types in schizophrenia. Further, recent experiments utilizing dual-label *in situ* hybridization have investigated the coincidence of GAD and parvalbumin (PV) or calretinin (CR). Since each type of GABAergic neuron in the PFC expresses only one of three calcium binding proteins, PV, CR or calbindin D-28, subdivision into three subtypes based on the presence of one of these proteins is possible. Using *in situ* hybridization, tissue samples from the PFC were labeled with probes for GAD and PV or CR, and direct correlations between GAD density and PV density were seen, whereas no correlation was seen between CR levels and GAD levels. Further insight into the relationship between GAD and PV RNA localization was achieved through dual labeling of cells with GAD and PV probes. In controls, GAD was often colocalized with PV, whereas, in schizophrenia patients, many cells expressing PV did not contain GAD mRNA. Other experiments have highlighted additional mRNAs that are downregulated in schizophrenia patients, such as those related to G-protein

subunits, glutamate receptors, synaptophysin, and other proteins involved in synaptic regulation.

Diagnosis of many neurological and psychiatric diseases occurs postmortem through examination of the morphology of brain tissue. More definitive diagnoses have been troublesome because of the relative lack of biomarkers for many diseases. By using well-prepared postmortem brain samples from patients, genomics and proteomics methodologies coupled with single-cell resolution may highlight the molecules and pathways involved in diseases like Alzheimer's and Parkinson's. It is hoped that such data can be deciphered and used for diagnostic purposes and eventually for possible treatments. In recent experiments, postmortem tissue from Alzheimer's patients was used to compare mRNA profiles in affected (tangle bearing) and nonaffected cells. qRT-PCR was used to compare quantities of synaptophysin mRNA, in patients and controls. Given the downregulation of synaptophysin in patient tissue samples, this RNA may serve as a new Alzheimer's biomarker.

A hallmark of Alzheimer's is the presence of intracellular protein aggregates called *neurofibrillary tangles* (NFT). It was hypothesized that differences in mRNA profiles existed in affected versus nonaffected cells. To investigate this, aRNA amplification from single tangle-bearing and nontangle bearing cells was used to generate probes that were used to screen microarrays. Large decreases in both amyloid-ß precursor as well as many dopamine (DA) receptor mRNA abundances were observed in the tangle-bearing neurons. Since these are all known to be involved in neurodegenerative diseases, this finding may be relevant to the etiology or propagation of the disease. Interestingly, lower levels of DA receptor binding (functional DA receptor) have previously been observed in Alzheimer's tissue; consequently, there appears to be a correlation between the functional and molecular studies. When working with a neurodegenerative disorder, it is important to note that decreases in RNA abundance may result from a decrease in cell number rather than from regulation of selected genes. Consequently, data showing that the RNA abundance for α1-ACT, a protein related to inflammation, is increased in Alzheimer's disease in single cells strongly suggests a link between inflammatory pathways and the disease state.

4 mRNA Localization

4.1 Targeting and Trafficking

Not only can there be variations in mRNA levels between cells but also within regions of a single cell. In neurons, subcellular regions such as dendrites, axons, and the cell soma can have different abundances of mRNA present. Similar nucleic amplification techniques can be used for analysis of cell subregion mRNA as are used for single-cell expression profiling studies. For example, individual dendrites can be manually harvested from a live neuron using a patch pipette and aspiration. The mRNA in the dendrite can be linearly amplified to quantifiable amounts using the same aRNA amplification techniques mentioned earlier. In recent studies, investigators have shown the possible differential distribution of large numbers of selective mRNAs in dendrites as compared to the cell soma. Since synapses on the dendrite are the place where the cell initially receives information from

presynaptic cells, it is reasonable to assume that the identity and abundances of dendritically localized mRNAs may be involved in the initial phase of some postsynaptic responses. This hypothesis is supported by the identification of some of the RNAs that are dendritically – targeted, such as those encoding NMDA, AMPA, and kainate classes of glutamate receptors, all of which are involved in postsynaptic responsiveness. Comparative analysis was performed on RNA that originated in the dendrites versus that of the soma. Differences in not only presence but also in quantity of some receptor subunits were observed between the two groups.

These data suggest several questions including the following: how do these differences in subcellular localization occur? Is the localization driven by differences in sequences such as the 3′-untranslated region (3′UTR) or are there RNA secondary or tertiary structural differences that help to target the mRNAs? Part of the answer comes from work investigating the somatodendritically localized microtubule-associated protein 2 (MAP2) mRNA. Normally, this RNA can be found in dendrites as well as in cell bodies (Fig. 2); however, if the 3′-UTR is removed, leaving just the coding and 5′-UTR, then the mRNA does not leave the cell soma. Also, if the 3′-UTR of the MAP2 RNA is fused to a nondendritically localized sequence, then the recombinant RNA is directed to the dendrites. It has now been shown that the 3′-UTR of many RNAs are necessary and sufficient for dendritic targeting. As our knowledge of RNA targeting sequences advances, the primary sequence as well as secondary and tertiary RNA structure will almost certainly be shown to influence RNA movement.

Advances in cell biological methodology are permitting experiments that monitor the real-time transport of RNAs into the dendrites to become feasible. An older method used pulse-chase experiments where RNA is made with incorporated radioactively labeled uridine (pulse) followed by chasing with nonlabeled uridine (chase). At different times after the chase, the movement of labeled RNA into different cellular regions can be observed. Also, visualization of the labeled RNA is done postfixing of cells, meaning that the observations are not made in real time. Further, the labeling used in pulse-chase experiments has been shown to change the stability of the mRNA. A vital dye, SYTO-14, fluoresces when it binds to nucleotides, making it possible to visualize RNA movement in live cells. RNAs were found to move at a rate of $0.1\,\mu m\,s^{-1}$, which is similar to the rate of transport when cargoes are moved along microtubules.

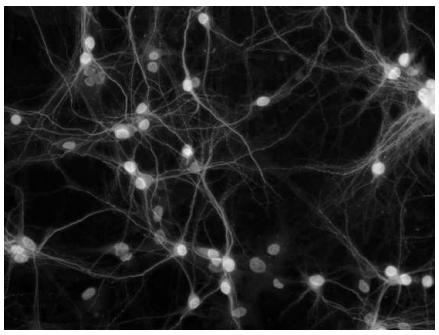

Fig. 2 Immunohistochemical localization of Map2 protein to the somatodendritic region of neurons – A rabbit polyclonal antibody raised against Map2 was applied to neurons of rat hippocampal neurons in primary culture. This first antibody was localized with a goat antirabbit secondary antibody that was fluorescein labeled (Green color). Green staining was observed in the fine hairlike structures that radiate from the cell soma. The nucleus is stained with DAPI. Glial cells in the primary cell culture system have a strong DAPI staining but no Map2 staining consistent with the absence of Map2 protein form glial cells (see color plate p. xxv).

Other types of tags can be used to visualize movement of mRNA such as a GFP-MS2 fusion protein that combines a fluorescent protein with the MS2 RNA binding protein. This is transfected into cells, and, when a fusion RNA construct is transfected into the same cells, the fusion protein binds to the engineered MS2 RNA sequence. Another *in vivo* marker of RNA is the molecular beacon probe, which is an antisense DNA oligonucleotide that is attached to a fluorophore and quencher. The structure forms a hairpin and binds with itself, quenching the fluorophore. When hybridization with the target RNA occurs, the hairpin is opened and fluorescence is emitted, allowing for very low background since only bound probes will fluoresce. This and modifications of the molecular beacon strategy are being used by several investigators to assess RNA trafficking in cells.

Different levels of mRNAs in dendrites as opposed to the cell soma have also been linked to developmental changes. For example, mRNA abundances have been monitored in dendritic growth cones through different stages of development. Amplification of RNA in growth cones at various stages of development followed by cDNA array analysis has identified RNAs that are present in the dendrite at each time point. As a function of developmental time, increasing numbers of the RNAs appeared in increased concentrations; others stayed in the soma for the entire time course of the experiment.

4.2 Translational Machinery

Even if there are different levels of mRNAs in dendrites, it is likely that much of actual cellular signaling takes place through the action of proteins. It is this rationale that suggests that dendritically localized mRNA may be translated into functioning proteins to facilitate dendritic-specific responses. Several years ago, in 1965, the ribosomal machinery necessary for protein translation was shown to exist in neuronal dendrites and to not be restricted to the cell soma. These data strongly suggested that localized translation could be a link to rapid changes in protein composition induced by synaptic modulation. This first observation of dendritically localized translational machinery was followed by several groups showing that polyribosomes localized preferentially near dendritic spines, the sites where synaptic connections with presynaptic neurons occurs. In further support of the dendritic protein synthesis hypothesis, other components of the translational machinery, including Golgi and endoplasmic reticulum, have been localized in dendrites. Currently, none of the intact neuron studies designed to prove dendritic protein synthesis have conclusively shown that protein synthesis can occur in dendrites. However, dendritic protein synthesis was confirmed using techniques to transfect isolated dendrites with exogenous RNAs encoding epitopes that when translated are immunologically or fluorescently detectable. These and subsequent studies have highlighted the complexities of dendritic protein synthesis and have further confirmed that integral membrane proteins can be synthesized and inserted into cellular membranes in dendrites.

5 Protein Profiling

While identifying changes in mRNA levels can give researchers a beginning point suggesting molecular causes of diseases or signaling pathway responses, it is usually

Tab. 2 Protein profiling.

	Quantitative	*Individual/population*	*Sample size*	*Simplicity*
Immunohistochemistry	No	Individual	Small	
Protein array	Yes	Population	Large	Advanced
IDAT	Yes	Individual	Small	
Mass spectrophotometry	Yes	Population	Large	Advanced

the protein abundances and their cellular localization that provides the most functionally useful information. Given that translational control of gene expression is a well-established fact, changes in mRNA levels do not necessarily correspond to changes in protein levels. RNA abundance differences suggest protein abundance differences but this should be viewed as hypothesis-generating data rather than as functionally causative biological changes. Measurement of cellular quantities of proteins and their posttranslational modifications will provide a more accurate picture of cellular responses to stimulation. Table 2 summarizes the different types of protein profiling techniques and the benefits and disadvantages of each method. Quantitative refers to whether the technique addresses just the presence of a protein or its cellular abundance. Individual/Population addresses whether specific antibodies are used or if the method is designed to measure many of the proteins present within the sample. Sample size refers to how much sample protein is required for the method. Finally, simplicity suggests how difficult the procedure is to use.

5.1 Immunohistochemistry

Understanding which proteins are present in a cell and at what concentrations can help researchers predict what the cellular response to stimulation will be or the results of aberrant stimulation such as occurs as a result of disease. Protein profiling in single cells is considerably more difficult than mRNA profiling because of the complexities of amino acid chemistry. However, methods for the evaluation of protein profile in a single cell are developing. The simplest way is to study the presence or absence of a certain protein using immunohistochemical techniques. In this methodology, antibodies that will bind to a particular protein are applied to a thin fixed-tissue section. The primary antibodies bind to the target protein and are detected with a secondary antibody that can be fluorescently tagged. The tissue is then microscopically analyzed and the presence of the protein visualized. By using different colors of fluorescence or other detection schemes, multiple proteins can be observed simultaneously. This process enables researchers to determine colocalization; if the proteins are colocalized, possible interacting proteins can be identified.

A recent example of the application of this methodology is shown in the examination of Lewy bodies (LB), which are intraneuronal protein aggregates involved in many neurodegenerative diseases such as Parkinson's and Diffuse Lewy Body Disease (DLBD). A major protein involved in LBs is known to be α-synuclein (α-syn), which is thought to interact with other proteins that have been linked to

these diseases. In other neurodegenerative diseases such as Alzheimer's, protein aggregates made of the protein tau are known as *Neurofibrillary Tangles* (NFT). Given the existence of aggregates in both diseases, it is reasonable to ask whether tau is localized to LBs. To address this question, immunohistochemistry was used to check for colocalization of α-syn and tau in LBs. Using a green fluorescent labeled (Cy3) antibody to detect one antigen and a red fluorescent labeled (Cy5) antibody to detect the second antigen, coexistence of the antigens was observed in the protein aggregates as the overlap of the fluorescence signal (yellow fluorescence). Eighty percent of the DLBD cases were found to exhibit coexistence of tau and α-syn in LBs. This high level of concurrency makes these proteins good candidates for biochemical analysis of protein interactions.

5.2 Protein Arrays

Other protein profiling techniques can provide quantitative analysis. Through the use of similar principles as microarrays, protein arrays or protein chips use protein binding as a way to separate and quantify proteins from single cells. There are two main ways for the initial protein targets to be attached to the array membrane. The first is to directly build the proteins on the arrays using a printing technique. The other way is to attach cDNAs to the membrane and run individual transcription and translation reactions, resulting in specific protein targets on the array. The latter technique eliminates worries of protein degradation and removes the need for protein purification before application onto traditional arrays. Protein arrays work on the principle of protein–protein interactions. Similar to coimmunoprecipitation, where antibodies are attached to beads and proteins that interact with the targeted protein are precipitated out of solution, protein microarrays allow for an initial screen of antibody–protein or protein–protein interactions. By applying the proteins from a single cell to known proteins on an array, it is possible to determine which proteins readily interact. Using fluorescently labeled probe proteins from cells, the amount of binding, and therefore the quantity of protein, can be measured. This method is useful when comparing protein profiles from disease and control samples. Similar methods use immobilized antibodies in place of target proteins to probe for labeled proteins.

The latest method in single-cell protein arrays uses what are called *nanoarrays*. These miniature spots use one-thousandth of the space that a traditional microarray spot occupies. This requires a much smaller probe and target protein samples which, in theory, makes it ideal for single-cell work. The current limiting factor to this method is that of detection sensitivity. A new technique called *Immuno-Detection Amplified by T7* RNA polymerase (IDAT) uses antibodies modified to contain a covalently attached double stranded DNA with an integral T7 RNA polymerase promoter. The anitbody binds to the antigen and this interaction is detected and quantified by T7 RNA amplification of the anitbody-attached DNA. The antibody is connected to a double-stranded oligonucleotide that contains a T7 promoter. This allows for specific amplification of the targeted RNA using the linear and quantifiable T7 RNA polymerase methodology.

5.3 Mass Spectrometry

Following protein array hybridization or traditional, two-dimensional gel electrophoresis to separate proteins, mass spectrometry (MS) can be used to definitively identify the proteins and their respective concentrations in the cells. Unlike fluorescently labeled proteins, MS techniques require no labeling, which eliminates any worries of labeling induced artifacts. Using only the proteins' masses and peptide fragment masses, MS separates and identifies proteins on the basis of time of flight (TOF) of fragments through the mass spectrometer. This procedure has been used successfully to identify and quantify down to 10 proteins from a single interacting target protein. In neurons, experiments using MALDI-MS have been performed to analyze the protein profiles of dendrites. Indeed, the advent of single-cell MALDI promises to identify the most-abundant proteins in the single-cell soma and potentially in isolated regions of the neuron.

6 Protein Localization

As previously emphasized, dendrites are the first areas of the cell to receive intercellular messages. Such intercellular communication causes overall changes in the cells that facilitate and result in complex brain function. The plasticity of synapses, or the ability of a neuron to adapt to different types of stimulation, is thought to be caused by changes in the abundance of locally functional proteins. It was historically thought that these changes occurred by transport of proteins from the soma; however, given the existence of dendritic protein synthesis, it is possible that differentially stimulated regions of a dendrite might respond in a subdendritic translationally selective manner. Experiments have been performed to address this issue in which isolated dendrites (free of the cell soma) were transfected with green fluorescent protein (GFP) mRNA so that local translation could be measured, *in vivo*, though observation of fluorescence. Interestingly, dendrites that were stimulated with the metabotropic glutamate receptor agonist, DHPG (a known stimulator of protein synthesis), exhibited an increase in fluorescence that could be blocked with a translational inhibitor, anisomycin. These experiments showed that the new GFP protein was being translated locally in the isolated dendrites. Further studies showed that the newly synthesized GFP was translated in hot spots that correlated with the location of ribosomes, which previously were shown to be preferentially located near areas of synaptic input. Also, data has been generated that shows that localized dendritic translational rates not only varied from those of the cell body but also within the dendrite. These heterogeneous and specialized translational activities of dendrites give insight into the signaling processes, which are likely involved in modulating the complex biology of intercellular communication within the brain.

7 Other Applications

7.1 Electrophysiological Measurements of Molecular Changes

The hippocampus is a brain region linked to learning and memory. It is also a region where neurogenesis, the generation of

new neurons, occurs. Experiments have been performed that connect these two facts, in an effort to understand the cellular events at the foundation of memory. Since new neurons are constantly being created in the hippocampus, there is always a subgroup of cells that are going through various stages of development. Investigators have determined the electrophysiological responses of neurons in each stage of development. The cells can be divided into five electrophysiologically distinct groups and single-cell RT-PCR was used to determine the developmental state of the neuron through the identification of stage-specific neuronal markers. Results showed that as development progresses, the hyperpolarity of the resting membrane potential of the cells increases and the input resistance of the cells decreases. The logical extension of these experiments is to identify the exact molecules and signaling pathways leading to these endpoints. This can be envisioned through the use of single-cell aRNA and microarray experiments coupled with proteomics.

7.2 Molecular Response to Cellular Input

One of the difficult aspects of psychiatric illness is the time course required for drug treatment to be effective. Most antipsychotic drugs take at least three weeks to begin to show their clinical efficacy. Drugs such as haloperidol are used for the treatment of diseases such as hyperactivity and mania and provide relief to the patient only if given chronically. Looking at gene expression profiles of cells that have been exposed to a drug can provide insight into the mechanisms resulting in the antipsychotic efficacy time-lag. In the rat model system, RNA was extracted from single cells in two different brain regions using LCM after administration of haloperidol for 1, 10, or 21 days. Radiolabeled aRNA was used to probe macroarrays containing 93 cDNAs of hypothesized relevance. After chronic administration, many of the mRNAs showed a steady baseline level or an increased expression level. At the intermediate time points, there were varying patterns. Some of the mRNAs spiked and later returned to a baseline level while others dropped far below the starting levels only to increase with chronic treatment. The complexities seen in the different patterns of time-dependent mRNA profiling suggest several avenues for dissection of the underlying reasons for the delayed efficacy in antipsychotic treatment.

8 Future Considerations

The last decade has seen an increase in the awareness of the importance of single-cell molecular analysis. The coordinate changes in mRNA abundance (transcription and degradation), protein abundance, posttranslational protein modifications, and the subcellular localization of RNA and proteins underlie all aspects of cellular functioning. As we progress into the twenty-first century, it is clear that we now need to not only quantitate the previously described issues *in vitro* but also to do so *in vivo*. Live cell imaging of biological processes such as transcription, translation, and subcellular movement will provide significant insight into normal cell functioning and subsequently into cell functioning as modified by disease state. To achieve these goals, it will be necessary for scientists in different disciplines to interact in an unprecedented manner. For instance, chemists making new fluorescent probes or other types of

molecular detectors, physicists helping to understand the folding dynamics of RNA and protein, and biologists defining the quantifiable correlates of cellular functioning will facilitate an understanding of *in vivo* biology.

Acknowledgment

The authors gratefully acknowledge Kevin Miyashiro for supplying Fig. 2 of this manuscript. This work was funded by NIH grants to J. Eberwine.

Keywords

African Apes
Chimpanzees, bonobos, and gorillas.

Anthropoidea
The so-called higher primates; the subordinal rank that subsumes New and Old World monkeys plus the hominoids.

Clade
A group of related organisms; a group of organisms united by common ancestry.

Derived Feature
A relative character state determined by how restrictively shared a feature under study is.

Hominids
Humans and their fossil relatives.

Hominoids
The group of anthropoid primates that includes gibbons and siamangs, chimpanzees, gorillas, orangutans, and humans.

Homology
Similarity due to common ancestry.

Large-bodied Hominoids
Orangutans, humans, and African apes.

Lesser (Small-bodied) Hominoids
The gibbons and siamangs.

Monophyletic Group
A clade.

Outgroup
A taxon that is outside of (a sister taxon of) the focal group of phylogenetic reconstruction.

Phylogeny Reconstruction
The generation of a theories of evolutionary relationships among taxa.

Primitive Feature
A relative character state determined by how broadly shared a feature under study is.

Primitive Retention
A feature that is shared by the members of a group by inheritance from a common ancestor.

Sister Taxon
A taxon that is the closest relative of another.

Systematics
The study of the pattern and relationships of organisms, including the identification of species and delineation of groups of taxa.

Taxic
Relating to taxa.

Taxon (Plural: Taxa)
Any taxonomic rank, for example, species, genus, family, order, and class.

Studies that rely on genetic and molecular information to address evolutionary questions fall roughly into two different categories: the reconstruction of the evolutionary relationships of organisms (including the times of divergence of groups or lineages), and the formation and emergence of morphological novelties that distinguish or characterize different organisms. The former endeavor is sometimes referred to as *molecular systematics*, and when it is applied to primates and especially the relatedness of humans and apes, ''molecular anthropology.'' The debate over the regularity of molecular change, resulting in a molecular clock, lies within the realm of molecular systematics, and especially that of molecular anthropology. In the past decade, in particular, the primary focus of molecular systematists has been DNA sequences, both nuclear and mitochondrial. Throughout, the assumption has been that the degree of similarity reflects the degree of evolutionary relatedness, because differences accrue once lineages have diverged from a common ancestor. The popularity of molecular systematics in recent years is also predicated on the notion of ''a law of large numbers,'' that is, the thousands of bases that produce DNA sequences. The question is whether these assumptions are sustainable.

The rather newly defined discipline of evolution and development, or ''evo-devo'' as it has been nicknamed, is less involved in the interpretation of molecular data for purposes of reconstructing evolutionary relationships than it is in trying to identify molecular elements – whether they be transcription factors or other kinds or classes of proteins, as well as ''genes'' themselves – that are relevant to, or participate in, the processes of development of structure and form. Here, what is important is not a particular RNA, DNA, or amino acid sequence, but the signal transduction pathways or sequences of communication between different molecules in the regulation of development and the origin of structure. Sometimes, hypotheses of when and at what level within groups of organisms specific features emerged are generated as a result of overlaying this information on a presumed theory of relationships of the organisms under consideration. It appears that insights from developmental genetics will prove to be more useful than sequence data alone for systematic and phylogenetic inquiry.

This entry will attempt to summarize the main aspects of these fields of inquiry, including their underlying assumptions, and suggest possible avenues for future research that might bring these disciplines together in light of new ways of thinking about evolution.

1 The Beginning of Molecular Systematics

The first inquiries into systematics and phylogenetic reconstruction by investigation of the "blood relationship" of organisms can be traced to a few individuals, of whom the best known is George H. F. Nuttall. In the research that preceded his monograph of 1904, *Blood Immunity and Blood Relationship: A Demonstration of Certain Blood-Relationships Amongst Animals by Means of the Precipitin Test for Blood*, Nuttall sought to demonstrate that the degree of similarity between animals in their blood serum proteins was a reflection of their evolutionary closeness. The idea was simple: produce an antiserum (antibodies or antigens) to blood serum proteins of one animal, mix the antiserum with blood serum proteins of another animal, and measure the amount of precipitin that settled out. The more profound the precipitation, the greater the similarity (because of a greater number of antibody–antigen binding sites), and, consequently, the closer the evolutionary relationship between the two organisms being compared.

The strength of the antiserum played an important role in determining just how many species might belong to the same group. A weak antiserum would provoke reactivity in the sera of only the most closely related of organisms, while a stronger solution would produce a precipitate when combined with the sera of a greater number of related animals. The more distantly related the groups being compared, the less the reactivity between serum and antiserum. In addition to strength of reactivity, Nuttall thought that the reaction rate was also an indicator of closeness of relatedness. In the end, he decided that "the zoological relationships between animals are best demonstrated by means of powerful antisera." Consequently, he concluded, "if we accept *the degree of blood reaction as an index of the degree of blood relationship* within the Anthropoidea [the so-called higher primates, New and Old World monkeys plus the hominoids, which includes gibbons, chimpanzees, gorillas, orangutans, and humans], then we find that the Old World apes are more closely allied to man than are the New World apes, and this is exactly in accordance with the opinion expressed by Darwin."

Although Nuttall believed that his approach accurately revealed the evolutionary relationships of animals, with the exception of reference in 1922 by the paleontologist, W. K. Gregory, to Nuttall having demonstrated "the anthropoid heritage of man," his work went largely unacknowledged until the 1960s, when various publications claimed to have demonstrated the evolutionary relationships of organisms through study of elements of their biochemistry.

2
The Molecular Assumption

Perhaps the most influential of these publications was by Emile Zuckerkandl and Linus Pauling on fetal and adult hemoglobin, which included a comparison of sequences between human, gorilla, horse, and fish. Although one might question the comparison of gill- with lung-bearing animals, the endeavor demonstrated that the fish was more dissimilar to humans than to the horse, while the gorilla was the most similar to humans in hemoglobin sequence. Since this pattern of taxic distance mirrored the morphologically accepted scheme of evolutionary relatedness of these animals, Zuckerkandl and Pauling suggested that their observations ''can be understood at once if it is *assumed* [emphasis added] that in the course of time the hemoglobin-chain genes duplicate, [and] that the descendants of the duplicate genes 'mutate away' from each other.'' From this assumption, they felt justified in proposing the following: ''[O]ver-all similarity must be an expression of evolutionary history,'' with descendants ''mutating away'' and becoming ''gradually more different from each other.'' In other words, the more time that elapses after a lineage's divergence, the greater the molecular difference its succession of descendants would accumulate. Consequently, evolutionary closeness became synonymous with molecular difference. Also assumed in this nexus of assumption is the notion of constant and gradual unilinear change.

There is, however, nothing in Zuckerkandl and Pauling's work that justifies the notion that ''overall similarity'' is ''an expression of evolutionary history.'' They merely assumed such a correspondence, just as they assumed that difference also meant change and the same kind of change, which, in turn, was achieved at a constant and gradual rate. However, the discovery of a hundred nucleotide differences between two taxa does not translate into the rate at which presumed substitutions occurred. One needs additional information, such as a suggestion of the time at which these differences began to accumulate. And then one has to assume that the rate of substitution over this period of time was gradual and that differences did not arise during a few concentrated phases of replacement.

Nevertheless, Zuckerkandl and Pauling's effort resulted in the ''molecular assumption'' – continual molecular change and its continual accumulation over evolutionary time – which would thereafter become the foundation of molecular systematics. As Adalgisa Caccone and Jeffrey Powell would write in 1989: ''Virtually all molecular phylogenetic studies. . .have a major underlying assumption: the genetic similarity or difference among taxa is an indication of phylogenetic relatedness. Lineages that diverged more recently will be genetically more similar to one another than will be lineages with more ancient splits.'' If one embraces the assumption, the rest may follow logically, but not necessarily because of biological demonstration. One of the major extensions of the ''molecular assumption'' is the notion of a ''molecular clock,'' the existence of which was promoted initially by Vincent Sarich and Allan Wilson.

Beginning with their first major paper in 1966, Sarich and Wilson sought to elucidate the evolutionary relationships of primates, and especially of humans and the large-bodied apes, using the technique of microcomplement fixation (MC'F), which requires only minute amounts of serum and antiserum for study of immunological

reactivity. Their molecule of choice was the larger blood serum protein, albumin. The degree of reactivity achieved between albumin and anti-albumin was translated into an ''index of dissimilarity,'' which was subsequently referred to as *immunological distance* (ID). The closer an ID value was to 1.0, the greater was the overall molecular similarity and thus, given an assumed equivalence between ID and evolutionary relationship, the presumption of closeness of relatedness between the organisms under study. As an apparent check on the validity of this approach, Sarich and Wilson conceived of the ''test of reciprocity.'' For example, if chimpanzee serum was cross-reacted with antihuman serum (produced by injecting another animal, for instance, a rabbit or chicken, with human serum) the first time around, human serum was cross-reacted with antichimpanzee serum the next time to see if the resultant ID values were reasonably similar. Predictably, the test of reciprocity usually confirmed the initial immunological finding.

The supposed evolutionary arrangement of the primates that Sarich and Wilson achieved was more consistent with the general pattern of primate relationships based on comparative morphology than it was in disagreement. Because of this concordance, they concluded that ''the MC'F data are in qualitative agreement with the anatomical evidence, on the basis of which the apes, Old World monkeys, New World monkeys, prosimians, and nonprimates are placed in taxa which form a series of decreasing genetic relationship to man.'' In 1967, in their second article on this topic, Sarich and Wilson argued that molecular change must have occurred at a constant rate among all major groups of primates. In the third and last article of this series, which was also published in 1967, they concluded that the small amount of difference they detected between hominoids in their albumin reflected little molecular change and that this, in turn, implied that little time had elapsed since the separation of the hominoid lineages. Since, as they claimed, molecular change ticked away at a constant rate, IDs represented a ''molecular clock'' that could reveal the times at which the various hominoids – actually any species – diverged and went off on their own evolutionary paths.

After calibrating the molecular clock on the basis of paleontologists' interpretation, based on fossils, of when the Old World monkey and hominoid lineages might have separated, Sarich and Wilson calculated divergence dates of about 10 million years ago for the gibbon lineage, eight million years ago for the orangutan lineage, and a mere five million years ago for the human and African ape lineages. The major implication of this calculation was that fossils older than five million years, such as *Ramapithecus* (now referred to the genus *Sivapithecus*) from c. 12- to 14-million-year old deposits in Indo-Pakistan, could not, as paleontologists concluded from study of morphology, be hominid.

However, while molecular systematists were in general agreement on the premise of the molecular assumption – that degrees of similarity reflect degrees of evolutionary closeness – not all of them embraced the notion of a molecular clock that ''ticked'' at a constant rate. Among the most vocal dissenters was Morris Goodman, who in the early 1960s was the leading proponent of Nuttall's work. Although Goodman went beyond claiming that molecular similarity indicated a very close relationship between humans and the African apes to advocating that these three hominoids should also be placed in the same taxonomic family, Hominidae

(a position that for years caused many comparative primate anatomists and paleontologists to be skeptical of molecular systematics in general), he nonetheless tried to accommodate the paleontologists' identification of pre-five-million-year old fossils as being hominid.

In contrast to Sarich (who in 1971 was the first molecular systematist to reject morphology as being phylogenetically informative), Goodman accepted the paleontologically derived date of at least 14 million years as the time of divergence between hominids and their potential ape relatives. As a consequence, though, Goodman then had to interpret the immunological and biochemical data in a way that would make them compatible with a deep timescale of hominoid diversification. He did so by constructing a selectionist argument to explain the apparent acceleration or deceleration in rates of molecular change that *de facto* must have occurred, given the paleontologically established dates for the earliest appearances of each of the large-bodied hominoids. Thus, for instance, if the various hominoid lineages had indeed originated between 18 and 14 million years ago, the extreme similarity between the various extant hominoids in their albumin had to have resulted from a slowdown in the rate of molecular change of that particular blood serum protein.

Goodman proposed that the inferred deceleration in rate of molecular change in large-bodied hominoid albumin was related to the fact that, although they are similar to other anthropoid primates in developing hemochorial placentation (the most intimate of placental modes in the approximation of maternal and fetal blood systems), large-bodied hominoids differ from other anthropoids in having very long gestation periods. He argued that in animals with hemochorial placentation but fairly short gestation periods, there would be enough slack in the system to allow unimpeded molecular change to occur and accrue. The fetus would be born before the mother's immune system could produce antibodies to it. A large-bodied hominoid's gestation period, however, would be long enough not only for maternal-fetal immunological incompatibility to build up but also for maternally produced antibodies to diffuse through the placenta, with deleterious consequences to the fetus.

The dilemma which then had to be confronted was: How could an animal have both hemochorial placentation and a long gestation period? Goodman's answer was that natural selection must have acted to reduce the possibility of immune responses from the mother toward her fetus's proteins. Consequently, there had to have been a slowdown of molecular change that was commensurate with a prolongation of the gestation period. Although albumin had been the basis of Sarich and Wilson's constant-rate molecular clock, Goodman used the same molecule as the exemplar of how the molecular clock could run at different rates.

Concurrent with the various approaches – immunological reactivity as well as gel-column electrophoretic separation – that were brought to bear during the 1960s and 1970s on the determination of evolutionary relationships was an increased interest in protein sequences. The first major study was Zuckerkandl and Pauling's 1962 analysis of hemoglobin, and, for some years thereafter, hemoglobin was the most intensely studied molecule. Beginning in 1973, however, a research group headed by A. E. Romero-Herrera analyzed myoglobin sequences across a number of primarily mammalian taxa. As more

taxa were added to the study, the resultant, most ''parsimonious'' arrangement of the hominoids placed the gibbon rather than the orangutan closer to a human-African clade. Only by arguing for a more complicated scheme of myoglobin ''evolution'' in hominoids – including, for instance, the condition that there had to have been various ''back-mutations'' to a state similar to the presumed unchanged state – could one arrive at the more commonly accepted arrangement of divergences: gibbon first, then the orangutan, and then a human-African ape group.

But while protein sequencing was seen by some, especially Zuckerkandl as late as 1987, as the molecular level on which to focus for purposes of determining evolutionary relationships (primarily because amino acid sequences are less subject to the problems with DNA, such as insertions, deletions, and back-mutations), there was a growing consensus that the best systematic information lay at an even deeper ''genetic'' level. Since base differences at the third position of a codon (a nucleotide triplet) did not yield different resultant amino acids, the concern of DNA sequence advocates was that demonstration of similarity in protein sequences could produce ''false'' phylogenies because the underlying nucleotide sequences themselves may be different. Consequently, it became imperative to get to the level of DNA – nuclear DNA – itself, especially because the general belief or at least expectation (which was based on bacteria and inferred for metazoans) was the existence of a direct correlation between specific DNA sequences and specific genes. And, as genes were conceptualized, there was also supposed to be correspondence between one or perhaps a few genes and a specific feature or structure. In addition, because DNA sequences were composed of thousands upon thousands of bases, the apparent massive scale of the comparison had the appeal of providing an overwhelming amount of phylogenetically relevant information.

3 DNA Hybridization

Although DNA sequencing was possible by the late 1970s, it was an expensive and laborious procedure, which made the endeavor itself, much less the comparison of DNA sequences for phylogenetic purposes, prohibitive. There was, however, another way in which DNA sequence information could be achieved: DNA–DNA hybridization.

The theory behind using DNA–DNA hybridization (or just DNA hybridization) as an approximation of overall similarity in DNA sequences between different taxa lay in the fact that if the two strands that form the helical structure of nuclear DNA were dissociated (which could be accomplished by subjecting it to heat), their complementary bases would rebond and the two strands would reform their original helical organization. However, it is not only two cleaved but also originally helically arranged DNA strands from the same individual that will reassociate (reanneal). Analogous to the geneticist Theodosius Dobzhansky's discovery earlier in the twentieth century with chromosomes of different lengths from different species of fruit fly, any two strands of DNA, from different individuals of even different species, will attempt to anneal.

As in Dobzhansky's fruit-fly experiments, in which the larger chromosome would loop and fold so that whichever of its loci were also present in the shorter one

would match up, single strands of DNA (derived from heat splitting or melting of a double helix) from different organisms would attempt to recombine or hybridize at complementary base positions. The more complementarity there was between hybridized DNA strands, the greater was the intensity of heat needed to break down the bonds holding them together. Consequently, it seemed logical to conclude that the heat (ΔT) it took to disassociate a DNA–DNA hybrid (that is, the more thermally stable the hybrid was), the more similar the annealed strands were in their nucleotide sequences. From this apparent demonstration, one could then invoke the molecular assumption to explain how higher ΔT's, reflecting greater molecular similarity, were also a reflection of closer evolutionary relatedness. As logical, though, as this thought experiment might appear to be, it relies on an assessment of overall similarity, which does not identify the bases or sequence positions that underlie differences in ΔT's. Conversely, similar ΔT's in different taxa might not be the result of the same regions hybridizing.

One of the first applications of the technique of DNA hybridization to evolutionary questions was published in 1968 by R. J. Britten and D. E. Kohne, who were primarily concerned with learning more about the genome. They discovered that the genomes of higher organisms – but not of bacteria or viruses – contained "hundreds of thousands of copies of DNA sequences." However, not only did repeated DNA sequences represent a considerable portion of a genome, Britten and Kohne also found that they were "trivial and permanently inert." Only a small fraction of a genome was composed of unrepeated, unique, single-copy DNA sequences, which apparently constituted the active or functional elements of that genome.

Britten and Kohne also speculated on pathways or mechanisms that might produce genomic change, which they argued must be considered on two different levels: change in nucleotide sequence, and the origin of new families of nucleotide sequences. As Zuckerkandl and Pauling had assumed for differences in hemoglobin, Britten and Kohne proposed that changes in nucleotide sequences – which would be identified as point mutations – occur slowly over time. However, this model would explain only the "divergence of preexisting families" of nucleotide sequences, not the introduction of new families of sequences, as was assumed would eventually happen in the gradual-accumulation-of-change model that dominated molecular systematics. The introduction of new families of sequences, Britten and Kohne alternatively suggested, must "result from relatively sudden events," called *saltatory replications*. Accordingly, "saltatory replications of genes or gene fragments occurring at infrequent intervals during geologic history might have profound and perhaps delayed results on the course of evolution." Although Britten and Kohne's distinctions between types of molecular change were not at the time embraced by molecular systematists, their suggestion of "saltatory replication" would certainly appear to have been borne out with the subsequent identification of vertebrate regulatory genes involved in segmentation – *Hox-a, Hox-b, Hox-c*, and *Hox-d* – as replicates of the orthologous *Antennapedia* gene identified in fruit flies.

One of the early attempts at using DNA hybridization to reconstruct relationships among the primates was published in 1976 by Raoul Benveniste and George Todaro, whose primary focus was actually on the distribution among mammals of the type C viral gene, the presence of which, they

discovered, was particularly characteristic of animals found in Asia, including the orangutan and the gibbon, but which, unexpectedly, was also present in humans. After reviewing these data, Benveniste and Todaro turned to DNA hybridization for sorting out the relationships of various primates. Relying on previous studies, they estimated "the effect of mismatched base-pairs on thermal stability" as being "between 0.7 and 1.7 °C per 1% altered pairs." Since, depending on the animal, nuclear DNA consists of anywhere from 10 to 100 million nucleotide pairs, every 1% of difference in nucleotide sequence between DNA hybrids would result in a drop of about 1.0 °C of the heat necessary to melt the hybrid molecule.

Although Benveniste and Todaro calculated a 1.1% sequence difference between humans and both African apes and a 2.4% difference between humans and the orangutan, their published ranges of ΔT's actually demonstrate overlap between all large-bodied hominoids (although one does not know the identity of nucleotide difference and similarity). Taking into consideration the fact that presumed-to-be-homologous DNA sequences are not the same length (that is, they do not consist of the same number of nucleotides) in all animals, including the large-bodied hominoids (see below for human and orangutan), one also does not know from DNA hybridization experiments the details of how a short sequence from one species aligns with a longer sequence of another species.

Probably because DNA hybridization seemingly provided a way of getting closer to the supposedly most "informative" genetic level, questions about what, exactly, similarity in ΔT's meant were not explored. But other questions were.

In the 1980s, Charles Sibley and Jon Ahlquist reviewed earlier DNA hybridization experiments and concluded that a major problem with them all was that only a limited number of cross hybridizations had been tested. This, Sibley and Ahlquist claimed, was the reason previous studies had such difficulty in refining certain evolutionary relationships, particularly those between humans and the African apes. Although there was not particular morphological support for this theory of relationship, molecular systematists often grouped these three hominoids together. However, the level of resolution in the majority of the molecular work was never fine enough to determine which two of the three hominoids were the most similar (and thus presumably the most closely related).

Sibley and Ahlquist felt another source of error in these earlier studies resulted from using all of an animal's DNA, repeated as well as single-copy, to form hybrids. They argued that it was important to remove all repeated DNA – since it was redundant – and to work only with single-copy DNA.

Before Sibley and Ahlquist decided to tackle the evolutionary relationships of the large-bodied hominoids, they had spent years applying their DNA hybridization technique to the phylogeny of birds, through which they also developed the notion of a uniform average rate of genomic change (UAR). UARs, they believed, characterized the nature of molecular, and thus evolutionary, change in all taxa. The notion of a UAR also seemed to negate the need for debates over constant versus irregularly running molecular clocks, which were directed at individual molecules. As they saw it, the entire genome could change at a uniform average rate, even though the rates

at which individual molecules change may be quite different.

Sibley and Ahlquist argued that the power of DNA hybridization in ''discovering'' the phylogenetic relationships of organisms came from sampling the entire genome of an animal. They claimed that, since an organism's genome is composed of millions of nucleotides, the ''law of large numbers'' provides the checks and balances necessary to rule out ''false'' similarities or parallelisms. Accordingly, since DNA hybrid strands will only link up along those stretches of sequences that are complementary, there should be no question about homology. Conversely, sequences that did not line up were not homologous. At least that was the argument.

Sibley and Ahlquist's melting temperatures for their DNA hybrids produced numbers, which they then converted into phylogenetic distances using a procedure called *average linkage*. ''Average linkage'' begins ''by clustering the closest pair or pairs of taxa,'' after which ''one links the taxa which have the smallest average distance to any existing cluster,'' and on it goes until ''all taxa are linked.'' The underlying assumption, which permits the linking of the most similar pairs, is that the DNA hybridization technique ''measures the net divergence between the homologous nucleotide sequences of the species being compared.''

Many aspects of Sibley and Ahlquist's phylogenetic reconstructions of birds were consistent with theories of relatedness derived from study of morphology. However, there were some significant differences, for instance, with regard not only to the broader phylogenetic relationships of, but also to the details of relatedness among, the flycatchers. By the 1980s, however, it was common practice, when molecular and the morphological phylogenies were in discord, to opt for the former. As Caccone and Powel argued in 1989, once the molecular assumption is accepted, overall similarity becomes the yardstick for determining closeness of relatedness. Indeed, whether it is a presumed albumin clock or a UAR, the assumption of ongoing molecular change validates the molecular assumption, which, in turn, demands that a molecular phylogeny is correct in its entirety, even if other sources of information contradict it.

Sibley and Ahlquist's ''law of large numbers'' and UAR appealed to most molecular systematists. This appeal was probably the primary reason paleontologists finally succumbed to the notion that molecular phylogenies had greater authority in deciphering evolutionary relationships when morphologically based theories were in conflict with them. But not all molecular systematists were convinced. Among them was Alan Templeton, who objected to the use of DNA hybridization because it did not allow one to determine the polarity of the similarity, which is necessary to address the question: ''Is similarity due to distant or recent common ancestry?'' For, only by studying the actual sequences of nucleotides can one determine the identity and from this attempt to infer the significance of similarity and dissimilarity. Sibley and Ahlquist countered, however, that there was ''no reason to expect data derived from base sequences to improve on those from amino acid sequences, which have produced contradictory results.'' In their support, they also quoted A. E. Friday (who had collaborated with Romero–Herrera on myoglobin sequencing): ''Phylogenetic conclusions derived from a study of nucleotide sequences will be subject to the same suspicions as those derived from amino acid sequences.''

4
Mitochondrial DNA

As the field of molecular systematics was expanding its sphere of investigation during the 1970s, DNA located outside the nucleus, in a cell's mitochondria, was attracting attention. In a study published in 1979, W. Brown, M. George, and A. Wilson noted that there was more difference between humans and a sampling of Old World monkeys in their mitochondrial (mt) DNA than there was among these same primates in their nuclear DNA. By assuming that the divergence between the human and Old World monkey lineages occurred over 20 million years ago (based on morphological studies of the primate fossil record), Brown et al. concluded that the differences between these humans and Old World monkeys could be explained if nucleotide substitutions occurred at a slower pace –5 to 10 times slower – in nuclear than in mtDNA (in other words, if mtDNA "evolved" 5 to 10 times faster than nuclear DNA). On the basis of this interpretation, Brown et al. calculated that mtDNA data are the most accurate for studying evolutionary events that occurred "within the past 3–10 million years."

In subsequent publications, they proceeded to analyze the mtDNA of the large-bodied hominoids, which, largely because of Sarich and Wilson's molecular clock, were assumed to have diverged within this time period and which, because of this assumption, were thus amenable to such analysis. Although their data showed the fewest differences (interpreted as substitutions) between humans and chimps, Brown et al. concluded that humans were related to an African ape group. Given the molecular assumption, however, the data should have yielded a human–chimpanzee sister group, as Maryellen Ruvolo and a number of collaborators concluded in 1991 from their analysis of mtDNA.

In addition to the fact that mtDNA is single-, not double-stranded, the allure of using mtDNA was and continues to be twofold. One assumption is that, unlike nuclear DNA, mtDNA is supposedly inherited only through the maternal line and thus not subject to the complexities that occur through recombination of maternal and paternal DNA. The second assumption is the existence of a "hotspot" in the D-looped configuration of mtDNA and that this is the primary site of molecular activity. This region is called the *hypervariable zone* and its study has been interpreted as providing evidence of evolutionary change. Although crucial to the use of mtDNA for purposes of phylogenetic reconstruction, these assumptions are probably incorrect.

The introduction of paternal mtDNA into fertilized eggs has been reported in the literature from time to time. For example, in 1992, Allan Wilson and coworkers demonstrated that this happens in mice, as part of the sperm's tail, which does contain mtDNA, penetrates the ovum's membrane. More recently, John Maynard-Smith and coworkers calculated that there had to have been a recombination of maternal and paternal mtDNA during human evolution, and concluded that this possibility should cause systematists to reconsider the seemingly inviolable "fact" that humans and chimpanzees are closely related.

As Erika Hagelberg reviewed at great length, there is increasing indication that mtDNA is not as exempt from paternal inheritance and recombination as was initially believed. With regard to so-called hypervariable sites being regions of preferentially high mutation rates, which therefore lend themselves to phylogenetic analysis,

Hagelberg pointed out that ''there is no direct evidence of hypervariability,'' although ''most researchers believe that anomalous patterns of DNA substitution are best explained by mutation.'' Indeed, she writes, ''because the notion of hypervariability fits with the received view of mtDNA clonality [maternal inheritance only], anomalies are seldom questioned.'' Hagelberg gives an interesting example. Depending on which subject's mtDNA is used, one can reconstruct ''our most-recent female common ancestor. . .[as having] lived just 6000 years ago, a date more consistent with Biblical Eve than Mitochondrial Eve.'' As she cautions: ''The picture is far from simple, and it is clear that extreme care must be taken in the interpretation of mtDNA phylogenetic trees in the face of possible recombination. . .[T]here are enough unexplained patterns in mtDNA data to warrant reassessment of the conclusions of many mtDNA studies.''

5 DNA Sequences

In spite of Sibley and Ahlquist's and Friday's warnings about nucleotide sequence data not being any more reliable than protein sequence data for reconstructing phylogenetic relationships, the increasing ease with which DNA could be sequenced could not be ignored by molecular systematists. Nuclear as well as mtDNA were sequenced. Regardless of the genetic ''level'' under scrutiny, the interpretation of similarity or difference in DNA sequences under comparison was still predicated on the molecular assumption. The weight of DNA sequence data as being key to deciphering evolutionary relationships assumed special significance in some areas of molecular systematics because of the supposed information content of nuclear DNA in general. As Elizabeth Bruce and Francisco Ayala wrote as early as 1979 in an article on blood serum proteins: ''Information macromolecules – that is, nucleic acids and proteins – document evolutionary history. . .[Thus] degrees of similarity in such macromolecules reflect, on the whole, degrees of phylogenetic propinquity.''

Almost coincident with the rise in popularity of comparing DNA sequences for purposes of inferring evolutionary relationships came the cautionary notes. Of particular importance in this regard is the question of alignment, which, in 1991, J. A. Lake was among the first to address. As mentioned above, not all DNA sequences chosen for comparison, if homologous (e.g. representing the same ''gene'' or segment) are the same length. Therefore, decisions must be made with regard to how to subdivide the shorter sequence in order to align its nucleotides with those of the longer sequence. Typically, the alignment of compared sequences is presented in the literature without justification of the assumptions and decisions that produced the alignment, which, in turn, was then used as the basis for the phylogenetic analysis. But, as Lake warned in the title of his article, ''[t]he order of sequence alignment can bias the selection of tree topology.'' In addition to assumptions that inform the decision to break up a short sequence so that its bases align with those of a longer sequence is the issue of whether, for one or another sequence, bases may have been added or inserted, removed or deleted, or one base substituted for another.

In *what it means to be 98% chimpanzee*, Jonathan Marks provides an example of these problems with DNA sequences from a human and from an orangutan to show three different ways in which

their bases (C,T,G,A) can be aligned and the interpretive consequences. Even beforehand, the assumption must be made that the 40 bases in the human sequence actually have homologous counterparts in the 54 bases in the orangutan sequence. There may be seven differences or there may be eleven differences, depending on how we decide the bases correspond to each other across the species – and that is, of course, assuming that a one-base gap is also equivalent to a five-base gap and to a base substitution.

As Marks comments:

"Tabulate the differences. The top one invokes five gaps and six base substitutions; the middle has only two gaps but nine base substitutions. And the bottom one has five gaps and only three base substitutions. The three pairs of sequences differ in the assumptions about which base in one species corresponds to which base in the other. While we might, by Occam's Razor, choose the alignment that invokes the fewest inferred hypothetical evolutionary events, we still have to decide whether a gap "equals" a substitution. Does the bottom one win because it has a total of only eight differences? Or might the middle one win because a gap should be considered rare and thereby "worth," say, five base substitutions?

The problem is that we cannot know which is "right," and the one we choose will contain implicit information about what evolutionary events have occurred, which will in turn affect the amount of similarity we tally. How similar is this stretch of DNA between human and orangutan?

In a more general sense, however, the problem of taking *quantitative* estimates of difference between entities that differ in *quality* is prevalent throughout the genetic comparison of human and ape. The comparison of DNA sequences presupposes that there are corresponding, homologous sequences in both species, which of course there must be if such a comparison is actually being undertaken. But other measurements have shown that a chimpanzee cell has 10% more DNA than a human cell. (this doesn't mean anything functionally, since most DNA is functionless.) But how do you work that information into the comparison, or into the 99.44% similarity [between human and chimp]?" [comment added].

These concerns have not, however, been widely appreciated by molecular systematists, especially molecular anthropologists, who not only portray the analysis of DNA sequences as neutral and objective but also use the assumption of relatedness to inform the way in which they analyze

the sequences they have aligned according to certain assumptions. Exemplary in this regard is the multiple DNA sequence analysis Maryellen Ruvolo and collaborators published in 1997, in which they sought to resolve the supposed dilemma of to which African ape humans are more closely related. In order to pursue this question, they assumed first that the orangutan was the sister taxon of a clade or evolutionary group consisting of humans, the chimpanzee, and the gorilla. Consequently, the differences in the orangutan had to be considered primitive relative to any similarities that were delineated between humans and one or the other of the African apes.

With the ever-growing popularity of the parsimony-based phylogenetic computer program PAUP (phylogenetic analysis using parsimony), it is common practice to ''root'' a phylogenetic analysis in a taxon that is chosen as the primitive outgroup – that is, the taxon that diverged earlier than the others – prior to the analysis taking place. Rooting parsimony or any of the other available clustering analyses (for example, nearest-neighbor joining or maximum likelihood, which are essentially similar to Sibley and Ahlquist's linking technique) in a particular taxon may be necessary for the algorithm to ''work.'' Nevertheless, this procedure artificially determines character polarity since, by definition, the outgroup (the taxon in which the tree is rooted) is defined from the outset as being primitive in its entirety. In turn, the taxa to which the outgroup is the supposed primitive sister taxon are predetermined as being derived in whatever ways they differ from it.

The widespread use of this algorithm-based approach to analyzing nuclear and mtDNA as well as protein sequences presents its own set of problems and assumptions. Consider the molecular assumption: Since molecular change is supposedly continually occurring and being accumulated as a lineage proceeds through time, the degree of molecular similarity reflects the antiquity or recency of lineage divergence. Accordingly, each lineage accumulates it own unique array of molecular changes, which should make a lineage more distinctive (that is, different) the longer it is in existence. Although tautological, this assumption explains why more recently diverged taxa are more similar than more anciently divergent lineages. On the other hand, in order to root an algorithm for purposes of generating presumed phylogenetic relationships, one must assume that the taxon chosen as the earlier-divergent outgroup is totally primitive relative to the taxa to which it is supposed to be the sister taxon. Yet, it is the molecular assumption that validates the use of overall similarity as the key to resolving phylogenetic relationships by contrasting it with the unique differences that earlier-divergent lineages accumulated along their own, unique evolutionary trajectories. Clearly, both assumptions cannot be correct at the same time. Either the earlier divergent-taxa or lineages did not change, but remained primitive (which is the logical extension of identifying a taxon as the outgroup in which to root a computer analysis), or they did change by accumulating their own suites of molecular difference (the basis of the molecular assumption), in which case they are at least in some aspects derived (and uniquely so, for that matter, because of their unique molecular histories) and not primitive relative to the taxa to which they are being compared.

In the realm of morphological systematics, according to Hennigian or cladistic

principles, overall similarity is not *de facto* a clue to evolutionary relatedness. Similarity must be sorted out into features that reflect a hierarchy of inheritance: primitive features from ancient ancestors, and derived features from recent ancestors.

Since the pattern of life is one of a hierarchy of nested sets of smaller and smaller clades (groups of related taxa), that which is considered primitive versus that which is considered derived depends on the level in the hierarchy of nested clades one is investigating. Primitive features – features retained in descendants – do not elucidate the relationships of these taxa. Only derived features can. It is also important conceptually to recognize that a derived feature at one level of the hierarchy is a primitive retention at another. There is no theoretical reason why this approach to systematics cannot be applied to molecular data. The major difficulty is that molecular systematists would have to sample and compare a wide range of taxa. This is the only way in which relative primitiveness and derivedness can be determined. It cannot be justified by *a priori* assumptions of directionality, as underlies the molecular assumption, or by choosing an outgroup on the basis of its presumed evolutionary relationship to other taxa. However, even from the beginning, it is also crucial to realize that shared similarity does not translate directly into a demonstration of relatedness. Taxa may be similar, not because they inherited changes that distinguished a recent common ancestor, but because they share primitive retentions, that is, features that have not changed in a succession of ancestors.

Nevertheless, it is becoming increasingly popular in the literature for molecular studies on the relatedness of taxa to be identified as being ''cladistic.'' One argument is that nucleotide bases – C, G, T, A – represent alternative character states. On one level this may appear logical, but it is actually misleading since none of them represents a character. Phylogenetically relevant alternative molecular character states would be better represented by comparison, for example, of arrangements of ''gene'' sequences with regard to *cis* and *trans* elements, patterns of introns and exons and of methylation of transposons or other elements, and pathways of molecular communication. Another argument in support of molecular studies being cladistic derives from the claim that molecular similarity is equivalent to synapomorphy; that is, shared similarity represents shared derived character states. This conclusion is, of course, only a restatement of the molecular assumption: the most recently diverged taxa share more recently accumulated (equate with derived) molecular states. Thus, the supposedly shared derived molecular states are delineated *a posteriori*; in other words, after the algorithm of choice has clustered taxa on the basis of their greater or lesser degrees of similarity (depending on the algorithm), typically after rooting the tree in a particular taxon (which, as pointed out above, at once defines it as being primitive and the taxa being compared to it as derived in their shared similarities). This, however, is not how a cladistic analysis proceeds. The endeavor of hypothesizing primitive versus derived character states occurs prior to hypothesizing relationships – which is the only way in which such a methodology can actually be employed.

The assumption of continual molecular change – whether through point mutations affecting nuclear or mtDNA, or altering amino acids in protein sequences – is also of interest. Recall that this idea was initially framed by Zuckerkandl and Pauling

as a way of explaining their data: ''overall similarity *must* [emphasis added] be an expression of evolutionary history,'' with descendants ''mutating away'' from each other, becoming ''gradually more different from each other.'' It is this assumption that proposes that earlier-divergent taxa accumulate their own molecular differences, while the most recently divergent taxa are similar because of the longer shared history of accumulated molecular changes and shorter time of independent molecular change. The existence of molecular clocks and UAR is predicated on this notion. Nevertheless, it must be recognized that this is an extrapolation – an explanation of how something might come to be. It has not been demonstrated.

The contradiction is that while constant molecular change is predicted through the molecular assumption as occurring during gametogenesis, or in some way as to be passed on to offspring, in molecular biology, it is well known that the only source of constant molecular change is ultraviolet radiation, which produces a mutation rate of 10^{-8}–10^{-9}. But the other element of UV-derived mutation is that it is random, with the potential of affecting either somatic or sex cells and also with regard to the molecule that is affected. Thus, while there might appear to be concordance between the reality of the physical world in which there is a relatively constant UV-provoked mutation and the concept of a constantly ''evolving'' molecular world, this is an illusion.

The notion of constant and accumulative mutation affecting sex cells is of further interest because it also contradicts the basic tendency of cells to remain in homeostasis. As seen, for example, in the roles of heat shock proteins (HSP) – maintaining cell membrane physical states through lipid transport, eliminating reading errors that occur during transcription or translation, DNA repair, chaperoning other proteins, and ensuring proper folding of proteins as they emerge from the ribosomes – the basic propensity of a cell is to resist change. Intuitively, this should make sense inasmuch as unabated molecular change would undermine the integrity of cell function, as would also be the case with a constant accumulation of point mutations, and more probably lead to the death of organisms than to change.

6 ''Evo-devo''

In 1975, Mary-Claire King and Allan Wilson surveyed all available data on blood serum proteins, as well as the results of DNA hybridization, with regard to humans and chimpanzees. Although their publication is cited as having demonstrated the relatedness of these two hominoids, this was not their intention. As they stated: ''the only two species which have been compared by all of these methods are chimpanzees. . .and humans,'' and thus ''a good opportunity is. . .presented for finding out whether the molecular and organismal estimates of distance agree.'' The result was that humans and chimpanzees differed in their genetic makeup only by about one percent. King and Wilson concluded that ''all the biochemical methods agree in showing that the genetic distance between humans and the chimpanzee is probably too small to account for their substantial organismal differences.'' In order to explain how humans and chimpanzees could be virtually identical in their genes but markedly different animals, King and Wilson suggested that humans and chimpanzees must be

different in those genes that regulate development.

Since then, studies on the regulation of development have expanded exponentially, not only with regard to distinguishing between regulatory and structural genes, but especially with regard to the array of molecules that induce gene transcription and communicate via signal transduction pathways to produce structure. Interestingly, those animals that have been studied in depth – such as the fruit fly, zebra fish, frog, chick, mouse, human – demonstrate a commonality of ''homeotic genes'' (which contribute to segmental patterning and segment identify). In turn, through their protein products (transcription factors), homeotic genes control or at least affect gene expression. Time and time again during development, the same proteins (e.g. various growth factors, trans-inducing and bone-modifying proteins) and regulatory genes (and their products) are coopted to produce what in adult organisms are different morphologies.

In 1994, Lewis Wolpert summarized the situation: ''During development, differences are generated between cells in the embryo that then lead to spatial organization (pattern formation), changes in form, and the generation of different cell types. Genes control development by controlling cell behavior.'' But one should not be too gene-centric in envisioning the emergence of form from genes and gene products alone. For, while there might be genetic regulation of some cells' activities, the results (e.g. cellular asymmetry, cell membrane elasticity or rigidity, compressive forces) might produce physical or mechanical responses, which may not themselves be genetically based, but which, nonetheless, greatly affect cell geometry and ultimately organismal form. ''Cell behavior,'' to return to Wolpert, has many different levels of meaning.

In the 1970s, Søren Løvtrup argued that one must recognize the importance of epigenesis in development: especially that changes in properties of the fertilized egg can alter the chronology and spatial organization of patterns of cellular diversification. Since the larger clades of multicellular organisms possess the same kinds of cells, as well as the same chemical substances that form the immediate environment of the cells, variation in the spatial and chronological organization of cellular differentiation must be at least one of the keys to the emergence of evolutionary novelty. For instance, whether a cell divides symmetrically or asymmetrically (which can be affected even by the positions of the chromosomes relative to the center or periphery of the cell) can greatly impact the spatial relationships of cells and, therefore, eventually have an effect on organismal shape. As Pere Alberch has emphasized, the development of organismal form and structure is also a function of the physical and mechanical properties of cells' sizes, shapes, and spatial relationships.

The application to evolutionary questions of discoveries in the regulation of development has given rise to the field of ''evo-devo'' (evolution and development), in which the interrelationship between the ''genetics'' and the ''epigenetics'' of development has become a primary focus. Indeed, Løvtrup's concern with the influence on metazoan development of differences in cellular differentiation during gastrulation appears to be even more germane to an understanding of the emergence of form and its conservation across taxa as well as of the emergence of differences in form, whether their expression constitutes variation (individual differences) or diversity (species differences).

7
Positional Information and Shape

One of the ongoing questions in developmental biology is how cells acquire positional information, not only in terms of entire structures themselves (e.g. where limbs will grow) but also with regard to how cells acquire information to contribute to regional shapes of a structure (e.g. the different segments of a limb).

In invertebrates, wing (e.g. as in a fruit fly) and limb (e.g. as in the brine shrimp-like crustacean, *Artemia*) positioning involves activation of the regulatory genes *nubbin* and *apterous*. In vertebrates, various regulatory genes, especially *Hox* genes, and also *dlx* (distal-less), are known to be involved in segmentation and limb positioning. In fish and tetrapods, the *Hoxd11-13* genes are expressed along the posterior margin of the enlarging limb bud; however, in tetrapods, this homeodomain expands anteriorly across the distal (lower) end of the limb bud. Additionally, in vertebrates, *Hox* genes are not only recruited in the formation of a segmented trunk but also through regional activation, in the segmentation of the hindbrain. Regional activation of *sonic hedgehog*, however, in part, underlies forebrain segmentation.

Eye development is also of interest in this regard. For although what used to be thought of as ''master-control genes,'' such as *Pax-6*, were found to participate in signal transduction pathways leading to eye formation in invertebrates (typically multilensed, rigid) as well as in vertebrates (single lensed, deformable), there is at least one element that vertebrates have in common: Even though there are differences among vertebrates so far studied with regard to when in ontogeny and how often and in how many different regions the *Rx* gene (which is also recruited in fruit-fly eye development) is activated, it is always expressed in the vertebrate forebrain. Thus, at one level, one can hypothesize that the last common ancestor of vertebrates was characterized by early activation of the *Rx* gene in the presumptive forebrain and that differences between taxa are the result of differences in other aspects of *Rx* gene expression: for example, the different proteins in the lenses of amphibians and mammals may be due in part to down- or upstream effects of the *Rx* gene being expressed later on in development in the amphibian (frogs) retina, whereas in mammals (mice), the *Rx* gene is expressed early on in the presumptive eye itself.

In addition to considering morphological differences in light of differences in regional (as well as in overlapping) domains of regulatory gene expression, it is becoming increasingly clear that differences in fields of molecular gradients (morphogenetic fields) also play a role. As C. Owen Lovejoy, M. J. Cohn, and T. D. White hypothesized in 1999 in their discussion of the evolution of human pelvic form, ''if a particular PI [positional information] gradient were to span *n* cell diameters, and those cells defined the ultimate anteroposterior dimension of the presumptive ilium (superoinferior in the adult human), then a slight increase in the steepness of its slope would cause that signal to span fewer cells, 'distorting' the presumptive anlagen and substantially altering downstream adult morphology.'' In other words, although it would seem to be a process involving myriad steps, ''the transformation of the common ancestral pelvis [in its entirety] into that of early hominids may have been as 'simple' as a slight modification of a gradient'' [comment added]. Thus, in addition to differences in gene expression and pathways of molecular communication,

as well as to the physical and mechanical consequences of cellular organization, morphological novelty in metazoans (and presumably plants as well) may also be affected by altering the domains of morphogenetic fields.

But what is the source of differences in gene or molecular gradient expression? Lovejoy et al. suggest that one need not seek the answer in mutation, which is a position that Sean Carroll has recently also strongly argued.

8 "Mutation"

The concept of ''mutation'' is about as slippery as that of a ''gene.'' It means different things to different researchers, and, interestingly, the differing concepts seem to ''work'' in their disparate intellectual contexts. With regard to mutation, the ''textbook'' notions of preceding decades included point mutation, gene duplication, and chromosomal rearrangement. The latter was basic to the earlier experimental studies and theoretical considerations of the fruit-fly geneticist, Theodosius Dobzhansky. Dobzhansky's emphasis on chromosomal rearrangement as a potential source of evolutionary novelty was subsequently adopted by the developmental biologist, Richard Goldschmidt, in his theory of systemic mutation, which he argued would lead to the abrupt appearance of novel form. Unfortunately, Goldschmidt is best remembered, and consequently criticized, for suggesting that such novelties would emerge in individuals he identified as ''hopeful monsters.''

One of Goldschmidt's major theoretical thrusts, however, was distinguishing between what he identified as micromutation (leading to variation and microevolution) and macromutation (leading to the origin of species or evolution). The small mutations that fruit-fly population geneticists, such as Thomas Hunt Morgan, inferred lay behind small phenotypic changes, Goldschmidt identified as micromutations, which, he argued, led only to the survival of species, not to their origin. The latter required a larger source of genetic disturbance, and for that he turned to chromosomal rearrangement. The logic is understandable: If the chromosome theory was correct (that, indeed, units of heredity or genes were contained on chromosomes – as Morgan presented it, like beads in a necklace), then manipulating them on a grand scale (producing a systemic mutation) might yield evolutionarily significant novelty, that is, new species. A major problem with Goldschmidt's theory, however, was that he did not provide a mechanism by which more than one individual would be the bearer of the novelty and, thus, of the systemic mutation underlying it.

Point mutations, commonly the result of UV radiation, are random with regard to affecting somatic or sex cells. In addition, if they do not interfere with cell function, such point mutations are not a reliable source of potential genetic and subsequently morphological novelty. Indeed, it appears that point mutations do not often cause any noticeable effect, either genetically or phenotypically. Gene duplication – as seen, for instance, in the emergence of *Hoxa-d* – does sometimes occur, but knockout experiments have demonstrated that duplication typically reflects redundancy, not a source of phenotypic novelty.

It may be true that manipulation of levels of thyroxin or retinoic acid during ontogeny can affect the size of an organism, or the shapes of some of its features, just

as a mother's diet can affect methylation in its fetus or fetuses, and thus aspects of her progeny's postnatal growth. However, these disturbances only affect an individual during its lifetime, and should not be expected to be repeated across generations and under the influence of fluctuating environmental stimuli (e.g. diet, temperature, amount of daylight). The problems, then, that still must be addressed are as follows: How does a genetic or cellular change remain "fixed" or constant, and how do many individuals come to bear it?

It is important to realize that there is a difference between change at the genetic level and what is perceived as phenotypic change. Common in the literature on the genetics of evolution is the mistake of conflating the two as constituting macromutation – a misconception that derives from the confusion Dobzhansky introduced with regard to the terms micromutation and macromutation when, in 1941, he sought to discredit Goldschmidt. Nevertheless, especially with the increasing awareness from molecular biology that there are not "genes for" features, we must be vigilant in making a distinction between what appears morphologically to have been the result of a macromutation (e.g. developing feathers instead of scales) and the underlying genetic–epigenetic interactive pathway.

9
Toward a Theory of Evolutionary Change

The question at hand, then, is the articulation of a mechanism that can first provide the potential for genetic novelty. Building on my original theory for the sudden appearance of morphological novelty (through the silent spread of recessive "mutations"), the molecular biologist, Bruno Maresca, and I have proposed that the opportunity for genetic novelty may lie in overstressing cells to the extent that their HSPs can no longer maintain genetic homeostasis; that is, they cannot fulfill their roles as chaperones, respond to the needs of the cell membrane, and, perhaps most importantly, for this discussion, properly fold other proteins and assist in DNA repair. Although first identified in heat shock experiments, HSPs can be affected by a variety of stresses, including diet (saturated vs unsaturated fatty acids), wind, aridity, and cold. Since most multicellular plants and animals possess HSPs, the theory is more widely applicable than metazoan-centric Darwinian and neo-Darwinians models of evolutionary change, the latter of which relies on unwarranted extrapolations from fruit-fly population genetics.

Since most multicellular organisms have a window of heat shock response, they can "adapt" to normal fluctuations in their environmental circumstances. If environmental change exceeds this window (as when seasons change), most organisms can "reset" it, often in less than two months. Until this window is reset, the stress induces an increase in HSP production. If, however, there is a spike in environmental stress that exceeds an organism's ability to reset its HSP response, HSP function will fail, and opportunities for introducing genetic novelty will emerge – especially as a result of improper protein folding and inefficient DNA repair. In the former situation, improperly folded proteins may, for example, no longer recognize (or be recognized by) promoter or enhancer regions to which they would normally bind, but they may now be capable of binding to different sites. An obvious result could be the activation or deactivation of a

''gene'' or ''genes,'' and, thus, the creation of one or more new developmentally significant signal transduction pathways. With regard to inefficient DNA repair, genetic novelty of a different sort can be introduced, with obvious potential consequences. In both cases, however, the fact that the environmental stress will be at least regional (if not global), the circumstances exist for more, perhaps many more, than one individual of a species to be affected (not, however, necessarily in the same way).

However, while it might be tempting to extrapolate immediately from these possible sources of genetic novelty to the emergence of evolutionarily relevant morphological novelty, one must be cautious. First, the effects of extreme environmental spikes on HSPs must be actualized during gametogenesis. If they are not, offspring will not be affected. Second, if the effects do not kill the individuals that inherit any of these genetically based novelties, they will probably not be expressed; that is, these genetic novelties will be in the ''recessive'' state. Consequently, there will not be an immediate phenotypic reflection of these genetic changes. In the recessive state, however, they can spread ''silently'' throughout the population, until it becomes sufficiently saturated with heterozygotes that homozygotes for the genetic novelty will be produced. If the resultant phenotypic expression – cellular or greater – does not kill its bearers, they may continue to reproduce themselves, as heterozygotes will also contribute to the numbers of individuals bearing the phenotypic novelty. Thus, the spread of a genetic basis for potential phenotypic novelty may take numerous generations before there is any statistical possibility of the phenotype being expressed. In other words, there will be a temporal disjunction between the disruption of cellular and genetic homeostasis, and what will be seen as the abrupt or sudden appearance of phenotypic novelty, and in some number of individuals. In addition, one must bear in mind that, during periods of ''silently spreading'' genetic novelty, there could be other environmental spikes that would contribute to the pool of potential for genetic novelty and also then phenotypic novelty (however defined). Superficially, this process – or at least the sudden appearance of phenotypic novelty – may seem macromutational, but, clearly, it is not, at least in the original sense of Goldschmidt or even that of Dobzhansky. Indeed, something as simple as slight changes in protein folding could have major cascading morphological effects.

10 Molecules and Systematics: Looking Toward the Future

It may be widely believed, and even true at some level, that, as Sean Carroll has recently reiterated, ''genomes diverge as a function of time.'' However, the observation that genomes may be different (in whatever ways difference, and similarity, may be identified and defined) does not in and of itself provide clues to how this difference was achieved. No doubt, some difference is due to the rare and random effects of UV radiation. In addition, genomic difference may be due to failures in DNA repair. There may be something intuitively appealing about Sibley and Ahlquist's the ''law of large numbers'' – the idea that organisms are closely related because they share ''lots'' of their genome. However, as Jonathan Marks points out, humans share

about 25% of their genome with bananas. Essentially, there is nothing in an observation of genomic difference or similarity that directly translates into the ''molecular assumption'' and, consequently, a theory of evolutionary relatedness.

Can, then, molecular information be useful in systematics and phylogenetic reconstruction?

The answer is yes, but it will have to be at the level of cell biology and pathways of molecular communication. As King and Wilson came close to predicting many decades ago, it is not through the study of molecular or genomic similarity of organisms that we will come to understand their biology, but through the investigation of those elements that underlie the development of their biology. This makes sense. For, if something as simple as the inactivation or deletion of a transcriptional enhancer can result in a more caudal repositioning of the sacrum, or if the expansion of a morphogenetic gradient can transform in its entirety a narrow pelvic girdle with tall, thin ilial blades into a broad, deep, and squat structure, then it is by seeking to identify the similarity or difference in these molecular events that we may more profitably explore the molecular basis of morphology and, consequently, the evolutionary relationships of complex organisms.

This is, perhaps, a timely occasion to both question and expand our perceptions of what is or will be evolutionarily revealing at the molecular level. There has been a steady increase in the number of studies that demonstrate virtual molecular identity between taxa that are morphologically very different and then express amazement at this apparent contradiction. As Sean Carroll pointed out with regard to the importance placed on the human and chimpanzee-genome projects – especially since so much money has been poured into them in the hope that forthcoming comparisons will instantaneously provide answers to any questions – demonstrating molecular similarity does not translate into deciphering the pathways that make these organisms so different in hard- and soft-tissue anatomy, physiology, reproductive biology, cognitive abilities, and behavior. Here, the ''law of large numbers'' fails to be enlightening. For, in contrast to the bacterial world, in the metazoan world, a one-to-one correspondence between a ''gene'' (a sequence of nucleotides bound by start and stop codons) and a ''gene product'' (a protein or amino acid sequence) is not there. In multicellular animals, RNA essentially directs the ''show,'' for example, in reading select bases and splicing specific introns, as it composes different proteins from the same stretches of DNA. The surprise ''The International Chimpanzee Chromosome 22 Consortium'' had at finding upon comparing human chromosome 21 with its apparent orthologue in the chimpanzee, chromosome 22 – not only that these hominoids differ by 83% in their amino acid sequences but also that this large difference is produced from very similar DNA sequences – should serve as a lesson: While there may be appeal to the ''law of large numbers'' that comparison of chromosomes and especially of entire genomes purportedly represents, in the end, this molecular level may not be the evolutionarily informative hotspot everyone has been seeking.

Keywords

Amyotrophic Lateral Sclerosis (ALS)
A neurodegenerative disease involving the selective degeneration of motor neurons in cerebral cortex, brainstem, and spinal cord. ALS was first described in 1869 by the French neuropathologist Jean-Marie Charcot.

Chaperone
A protein that assists in the folding or assembly of another protein, without becoming part of the completed structure.

Guanine Nucleotide Exchange Factor (GEF)
A protein that facilitates the exchange of GDP for GTP in a GTP-binding protein.

Superoxide Dismutase 1 (SOD1)
An enzyme that catalyzes the conversion of superoxide anion to water and hydrogen peroxide.

Motor neuron diseases are human disorders characterized by the progressive degeneration and death of motor neurons and the denervation of skeletal muscles. Their course is always fatal and there are currently no really effective therapies. While most adult motor neuron diseases appear sporadically, others are inherited, because of genetic mutations in Superoxide Dismutase 1, Alsin, or Dynactin, or associated with risk factors such as genetic polymorphisms in Neurofilaments or Vascular Endothelial Growth Factor (VEGF). Multiple molecular mechanisms might therefore cause – or contribute to – disease. Some of the proposed disease mechanisms might operate cell-autonomously in motor neurons, for example, by perturbing energy metabolism, endosome trafficking, or axonal transport, whereas others seem to act indirectly, involving nonneuronal cells and diffusible factors such as nitric oxide and excess glutamate. Relevant cellular and animal models are now available to test these hypotheses and to investigate new therapeutic strategies.

1 Human Motor Neuron Diseases

Motor neuron diseases represent a spectrum of disorders in which neurons controlling voluntary movement progressively degenerate while other types of neurons are spared. Degeneration of upper motor neurons in cerebral cortex results in spasticity and hyperreflexia. Degeneration of lower motor neurons in brainstem and spinal cord leads to muscle paralysis

and atrophy. According to these clinical and pathological criteria, motor neuron diseases can be further classified: Amyotrophic lateral sclerosis (ALS, Charcot disease or Lou Gehrig's disease) affects both upper and lower motor neurons. An ALS form with predominant brainstem symptoms is called progressive bulbar palsy. Progressive muscular atrophies represent conditions in which only lower motor neurons degenerate, whereas primary lateral sclerosis involves only upper motor neurons. ALS is the most frequent motor neuron disease in the adult, with a lifetime risk of 1 in 2000 and a mean age of onset around 55 years. ALS is inevitably fatal but its course is variable between patients. Death is most often caused by failure of respiratory muscles appearing within one to five years after diagnosis.

Histopathological studies have documented a loss of motor neurons in the cervical and lumbar spinal cord of ALS patients. The number of myelinated large caliber axons in the corticospinal tract and in the ventral roots was also found to be reduced and signs of Wallerian degeneration and atrophy have been noted. Other microscopic abnormalities such as reactive gliosis, neuronal inclusion bodies, axonal spheroids, and the loss of dendrites have also been described. In skeletal muscle, denervated fibers appear atrophic and angulated. Grouping of muscle fiber types positive for esterase, ATPase, or myosin isoforms indicates muscle reinnervation from the remaining motor neurons.

2 Genetics of Motor Neuron Diseases

While most ALS cases appear spontaneously, some (~10%) are familial (FALS). These can show autosomal dominant, recessive, or X-linked inheritance. Genetic studies in FALS (familial amyotrophic lateral sclerosis) are rendered difficult by the late onset of disease, its incomplete penetrance, and the short survival of affected family members. Nevertheless, several FALS genes have been identified (Table 1) and additional FALS loci have been mapped to chromosomes 9q21-22, 15q15-22, 16, 18, and 20.

Tab. 1 Gene mutations responsible for motor neuron diseases.

Gene	*Disease*	*Locus*	*Inheritance*	*Mutation type*
SOD1	ALS1	21q22.1	Dominant[a]	Missense
Alsin	Juvenile ALS (ALS2) progressive lateral sclerosis	2q33	Recessive	Frameshift
Tau	ALS/dementia/ Parkinson complex	17q21	Dominant	Missense or intronic
Dynactin (p150 subunit)		2p13	Dominant	Missense
Androgen receptor	Spinal and bulbar muscular atrophy (SBMA)	Xq12	Recessive	CAG triplet expansion
Survival motor neuron (SMN)	SMA	5q13	Recessive	Deletion or missense

[a]With the exception of SOD1 D90A.

2.1 SOD1 Mutations

About 10 to 20% of familial ALS cases (1–2% of total) are linked to mutations in the superoxide dismutase 1 (SOD1) gene. The *SOD1* gene is ubiquitously expressed and encodes a dimeric enzyme containing 153 amino acids, one copper, and one zinc ion per monomer. The normal function of this enzyme is to catalyze the conversion of superoxide to hydrogen peroxide. Over 100 different missense mutations scattered throughout the protein have now been shown to produce motor neuron disease. All SOD1 mutations except one (D90A) show autosomal dominant transmission. It has been proposed that SOD1 mutations cause motor neuron degeneration by catalyzing aberrant free radical chemistry, by perturbing energy homeostasis, by initiating protein aggregation, by causing excessive glutamate levels, or through a combination of these mechanisms.

2.2 Alsin Mutations

Mutations in a gene termed *ALS2 or Alsin*, located on chromosome 2q33-35, have been detected in familial ALS cases with juvenile onset and slow disease progression. The gene mutations are autosomal-recessively inherited and most of them represent small deletions. Computer algorithms have predicted that the Alsin protein contains guanine nucleotide exchange factor (GEF) domains for small GTPases. Small GTPases are molecular switches that cycle between an inactive GDP-bound and an active GTP-bound state; they are activated by GEFs, which stimulate the exchange of GDP for GTP. The 183-kDa alsin protein acts as guanine nucleotide exchange factor for the small GTPase Rab5, localizes to early endosomes, and enhances their fusion. Reported alsin mutations are predicted to result in a failure of Rab5 activation, suggesting that normal endosome fusion and trafficking are essential for motor neuron maintenance.

3 Culture Models of Motor Neuron Degeneration

In an attempt to unravel disease mechanisms and to identify or validate new therapeutic candidates, various motor neuron culture models have been developed. These include neuronal cell lines, primary motor neurons, and spinal cord slices.

3.1 Neuronal Cell Lines

Neuronal cell lines, derived from tumors or *in vitro* transformed cells, only rarely resemble motor neurons. One of these exceptions is the NSC-34 cell line, which was generated by fusion of mouse neuroblastoma cells with embryonic spinal motor neurons. Like motor neurons, NSC-34 cells display a multipolar phenotype and express choline acetyltransferase (ChAT), different ion channels, and neurofilaments. These cells can also generate action potentials and induce acetylcholine receptor clusters on cocultured myotubes. NSC-34 cells transfected with mutant SOD1 plasmids display various abnormalities including mitochondrial dysfunction, increased cytochrome c release, and decreased cell survival following oxidative stress. Gene expression profiling and proteome analysis revealed underlying molecular changes such as downregulation of neurofilaments

and glutathion S-transferases and upregulation of proteins involved in NO metabolism (argininosuccinate synthase, argininosuccinate lyase, and neuronal NO synthase). Some of these changes could be confirmed *in vivo* in individual spinal cord motor neurons.

3.2 Motor Neuron Cultures

Motor neurons are notoriously difficult to purify and to maintain in primary culture. Current methods rely on three properties of these cells: their characteristic size, their expression of specific surface markers, and their dependence on trophic factors for survival and neurite outgrowth. Since motor neurons are larger in size and lower in density than most other types of neurons and glial cells, they can be enriched by differential centrifugation. As a further purification step, immuno-panning techniques for chicken and rat spinal motor neurons have been developed using monoclonal antibodies that recognize specific cell surface antigens such as SC1, BEN, or the p75 neurotrophin receptor. Spinal motor neurons can also be isolated using antibody-coated microbeads and subsequent magnetic cell sorting. Once purified, motor neurons are seeded in culture dishes coated with appropriate substrates such as polyornithine and laminin. While many motor neurons die during the first hours of culture, the remaining cells develop typical morphologies and are able to survive for several weeks when appropriate trophic factors are added. These procedures are currently limited to embryonic motor neurons from spinal cord and brainstem and not yet available for isolating cortical motor neurons.

One of the first motor neuron culture systems relevant to human ALS involved microinjection of mutant and wild-type SOD1 plasmid expression vectors into cultured motor neurons. In this system, abnormal protein aggregates appeared specifically in mutant SOD1-expressing cells. Newer studies suggest that cell death of SOD1 expressing motor neurons might also involve external triggers: In normal embryonic motor neurons, activation of the cell surface receptor Fas triggers death via two parallel pathways, the classical FADD/caspase-8 cascade and a second cascade involving Daxx, ASK1, p38, and transcriptional upregulation of neuronal NO synthase; see Fig. 1. Interestingly, motor neurons from transgenic mice for the SOD1 mutations G37R, G85R, or G93A are much more sensitive to Fas- or NO-triggered cell death than motor neurons expressing wild-type human SOD1. Cerebellar neurons, DRG neurons, or astrocytes do not display such increased sensitivity, reflecting the selective vulnerability of motor neurons in living mutant SOD1 mice. Despite their inherent technical difficulties, mutant SOD1 motor neuron cultures thus emerge as a promising tool to screen pharmacological compounds for their effects on disease-related molecular targets or cellular phenotypes.

3.3 Spinal Cord Slice Cultures

In an attempt to study motor neurons in their normal cellular environment, several groups have prepared spinal cord slice cultures from rat and mouse. These cultures can be maintained for up to 2 weeks (adult mouse) or even several months (perinatal rat). Individual motor neurons in living slice cultures are identified by their large size, the presence of action potentials, or retrograde DiI labeling prior to culturing. In fixed slices, motor neuron cell bodies

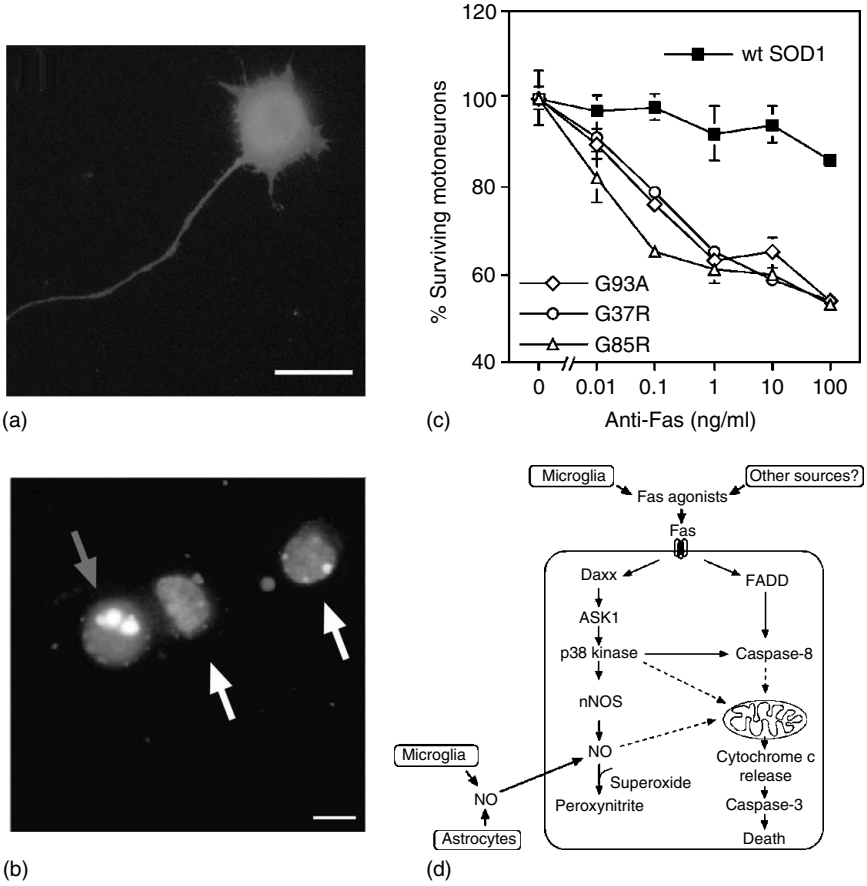

Fig. 1 Isolated motor neurons can be used to study mutant SOD1-linked motor neuron death. (a) Human superoxide SOD1 is expressed in cultured embryonic motor neurons from transgenic SOD1 G93A mice. (b) Treatment of SOD1 G85R motor neuron cultures with agonistic antibodies to the cell surface receptor Fas leads to increased apoptosis, as detected by staining with DAPI (in blue) and immunolabeling for activated caspase 3 (in red). An apoptotic motor neuron with strong caspase-3 activation and nuclear condensation c (red arrow) can be distinguished from healthy motor neurons displaying only weak caspase-3 activation and normal chromatin structure (white arrows). Scale bars: 25 µm. (c) Motor neurons from transgenic mutant SOD1 G93A, G85R, and G37R mice show higher susceptibility to Fas-triggered cell death than motor neurons from mice expressing wild-type SOD1. (d) Model of Fas-triggered motor neuron death. Cell death involves the classical FADD/caspase-8 pathway and a parallel pathway leading from Daxx, ASK1, and p38 activation to transcriptional upregulation of neuronal NO synthase (nNOS) and NO production. The presence of mutant SOD1 sensitizes motor neurons to Fas agonists and NO. Potential sources for these cell death triggers are astrocytes and microglia. (See color plate p. xxvi); see Fig. 2.

can be identified and counted by Nissl staining or immunocytochemical labeling for the neurotransmitter-synthesizing enzyme ChAT, the transcription factors Islet 1/2, or the surface receptor Ret. Slice culture systems have also been developed for the study of cortical motor neurons.

In the context of ALS research, organotypic culture systems have been used to show that chronic inhibition of glutamate uptake can cause slow degeneration of motor neurons. In this model, antiexcitotoxic agents such as CNQX, riluzole, and topiramate, nitric oxide synthase inhibitors, and neurotrophic factors such as IGF-1 and GDNF protected against motor neuron degeneration. When organotypic slice cultures were derived from transgenic mutant SOD1 mice and exposed to excitotoxic stimuli, mutant motor neuron death could be blocked with a cyclo-oxygenase-2 inhibitor. In another spinal cord slice model, chronic administration of malonate, an inhibitor of mitochondrial electron transport, was found to induce motor neuron death, which could be prevented by a number of antiexcitotoxic agents, antioxidants, and caspase inhibitors.

4 Animal Models of Motor Neuron Degeneration

4.1 Axotomy Models

In neonate animals, motor neuron death can be experimentally induced by a peripheral nerve lesion, since developing motor neurons depend for their survival on contact with their target muscle and their axonal environment. In the most widely used models, the sciatic, facial, or hypoglossal nerve is crushed or sectioned, and the survival of the lesioned motor neurons is eventually after prior retrograde labeling. The extent of motor neuron death depends on the age of the animal and the type of lesion. When a sciatic nerve lesion is performed in 1-day old rats, 90 to 100% of the corresponding motor neurons are lost. When the same type of lesion is performed at 4 or 5 days of age, between 80 and 100% of the motor neurons survive. Lesioning the peripheral nerve by section or close to the cell body both results in slower target reinnervation and reduced motor neuron survival, as compared to lesioning the nerve by section or distally.

Axotomy-induced motor neuron death has many apoptotic features. Morphological studies on lesioned motor neurons have provided evidence for DNA fragmentation, nuclear condensation, and mitochondrial disruption. Pharmacological inhibition of caspases or mitochondrial pore proteins or overexpression of apoptosis-inhibitory proteins (IAPs) reduced the extent of axotomy-induced motor neuron death. Finally, genetic studies in transgenic mice showed that overexpression of the anti-apoptotic gene *Bcl-2* or deletion of the proapoptotic gene *Bax* protected against axotomy-induced cell death. It has also been recognized that apoptotic death of axotomized motor neurons involves activation of cell surface receptors (TNF-R and Fas) and intracellular production of nitric oxide.

4.2 Transgenic Mutant SOD1 Mice and Rats

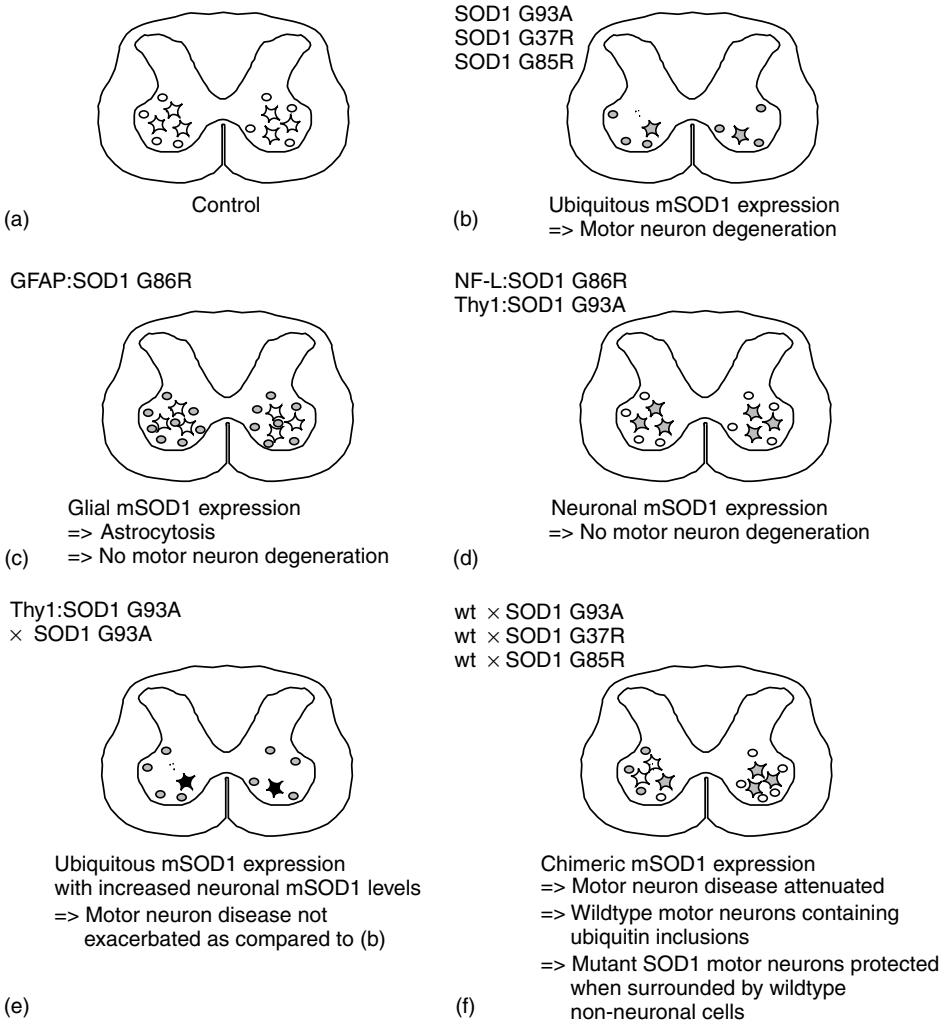
One breakthrough in ALS research has been the generation of transgenic mice and rats expressing human ALS-linked SOD1 mutations. Several transgenic lines show clinical, histopathological, and electrophysiological signs closely resembling

human motor neuron disease. Transgenic mice for the SOD1 mutants G37R, G85R, or G93A display progressive muscle atrophy and paresis, gait instability, and premature death. Similar symptoms were observed in transgenic rats expressing the SOD1 mutants G93A or H46R. In these animals, disease severity depends on the type of mutation, the number of transgenes, and the genetic background. Affected mice display a reduction in the number of spinal motor neuron cell bodies and motor axons and, to a more variable extent, astrogliosis. Other histopathological abnormalities include a fragmented Golgi apparatus, enlarged mitochondria, and various types of inclusions. Electrophysiological studies in mutant mice revealed the presence of fasciculations and fibrillations, and a decreased number of functional motor units.

Some of the molecular consequences of mutant SOD1 expression in mouse spinal cord have also been recognized: sequential activation of caspases, upregulation of apoptotic proteins such as Bad and Bax, release of cytochrome c from mitochondria, and deregulation of the cyclin-dependent kinase cdk5. How the SOD1 mutants cause these changes is still obscure. For the following reasons, altered SOD1 enzymatic activity does not seem to be causal: first, only some disease-causing SOD1 mutations are enzymatically inactive (e.g. G85R), while others retain activity (G93A or G37R). Second, no motor neuron disease is observed when SOD1 activity in mice is lowered (by knocking out the *SOD1* gene or the *CCS* gene required for SOD1 copper loading) or when SOD1 activity is elevated (by transgenic expression of wild-type SOD1). Finally, crossing transgenic mutant SOD1 mice with SOD1 knockout mice, transgenic mice overexpressing wildtype SOD1, or CCS knockout mice, has no influence on disease.

The cellular basis of mutant SOD1 toxicity also remains enigmatic: In transgenic mice, pathology is only observed when mutant SOD1 expression is ubiquitous in all cell types but not when it is restricted to astrocytes or neurons (Fig. 2). To rule out insufficient levels of transgene expression, chimeric mice have been generated that carry mixtures of wild-type and mutant

Fig. 2 Motor neuron degeneration in transgenic ALS mice is influenced by nonneuronal cells. The consequences of mutant SOD1 expression in different cell types are schematically illustrated on spinal cord cross sections. Genotypes of transgenic mice are indicated. Motor neurons are depicted as multipolar cells and glial cells as round cells. Mutant SOD1 expression in these cell types is indicated in gray or black, normal (endogenous) SOD1 expression is shown in white. (a) Normal situation. (b) In transgenic mice, ubiquitous expression of mutant (m) SOD1 causes typical motor neuron disease. (c, d) No disease is observed in transgenic mice expressing mutant SOD1, specifically in glial cells (c) or in neurons (d). (e) Crossing of Thy1: SOD1 mice with transgenic SOD1 G93A mice elevates mutant SOD1 levels (in black) in motor neurons above the ubiquitous expression levels but does not exacerbate disease. (f) Chimeric mice that carry a mixture of wild-type (wt) and mutant SOD1-expressing cells in their spinal cord show later disease onset and longer lifespan than their mutant littermates. These improvements correlate with the proportion of wild-type cells within individual spinal cords. Ubiquitin inclusions are found not only in mutant but also in wild-type motor neurons. Interestingly, mutant SOD1 motor neurons in the chimeras seem to be protected by wild-type nonneuronal cells in their environment. Taken together, these data suggest that motor neuron degeneration is the result of a complex interplay between motor neurons and surrounding nonneuronal cells.



SOD1 expressing cells in the spinal cord. Interestingly, in these chimeras, degenerative signs such as ubiquitin inclusions are found not only in mutant SOD1 expressing motor neurons but also in wild-type motor neurons. Moreover, survival of mutant motor neurons seems to be enhanced by the presence of nonneuronal cells. These observations suggest that motor neuron degeneration can be triggered by non-cell-autonomous mechanisms.

4.3 *pmn* Mice

Mice with progressive motor neuronopathy (*pmn*) represent another popular motor neuron disease model. Homozygous *pmn* mice develop first neuromuscular symptoms at 2 weeks of age, i.e. much earlier than all reported mutant SOD1 mice. The *pmn* disease manifests with hindlimb atrophy and paresis and rapidly extends to

the forelimbs and other muscle groups. Affected *pmn* mice die around 40 days of age, most probably from respiratory failure. They display fibrillations, a loss of axons in motor nerves and ventral roots and a reduced number of motor neurons in some brainstem nuclei. The genetic defect was identified as a point mutation in the *Tbce* gene, which encodes a chaperone protein for tubulin folding and microtubule assembly. The *pmn* mutation results in decreased Tbce protein stability, diminished concentrations of tubulins in peripheral nerves, and progressive loss of microtubules. Interestingly, Tbce gene mutations have also been discovered in human patients with Sanjad Sakati/Kenny Caffey disease, a rare hereditary syndrome comprising hypoparathyroidism, mental retardation, facial dysmorphism, osteosclerosis, and fulgurant infections. It is thus conceivable that the dramatic human disease course obscures motor neuron disease symptoms or that the human Tbce mutations impair another Tbce protein function than the mouse mutation.

4.4 Mutant VEGF Mice

Vascular endothelial growth factor (VEGF) is a secreted 165 amino acid protein that controls the growth and permeability of blood vessels. Under conditions of low oxygen tension, VEGF is upregulated by specific transcription factors that act on a hypoxia-responsive element located in the VEGF promoter. Mice with a targeted deletion of this hypoxia-responsive element are unable to induce VEGF in response to hypoxia. Surprisingly, these mice manifest typical signs of motor neuron degeneration at an age of 5 to 7 months, with progressive muscle atrophy, impaired motor performance, and loss of motor axons and endplates. Interestingly, three polymorphisms in the human VEGF seem associated with reduced levels of plasma VEGF and an increased risk for ALS. These studies incriminate VEGF as an ALS-modifier gene. Whether VEGF acts directly as a trophic factor for motor neurons or more indirectly, by modifying spinal cord vasculature or perfusion, is currently under investigation.

5 Therapeutic Approaches to Motor Neuron Diseases

5.1 Studies in Animal Models

In the past decade, more than 100 different therapeutic approaches have been tested in animal models of motor neuron degeneration. Lesion models have been instrumental in validating neurotrophic factors as therapeutic candidates: CNTF, BDNF, NT-4/5, GDNF, and CT-1 all enhanced survival of motor neurons after axotomy. More recently, several pharmacological compounds such as deprenyl, a monoamino-oxidase B inhibitor, MK-801, a glutamate receptor antagonist, CGP3466B, a GAPDH antagonist, and riluzole were also shown to be neuroprotective in these models.

In mutant SOD1 mice, numerous compounds have been tested but only few have resulted in robust positive effects (Table 2). Following treatment with riluzole, currently the only FDA-approved drug for ALS, the mean survival of SOD1 G93A mice was improved by 11% but histological or functional effects could not be documented. Feeding the animals with creatine also increased survival and provided some motor neuron protection. Numerous ALS

Tab. 2 Selected therapeutic trials in mouse motor neuron disease models.

Treatment	*Model*	*Delivery*		*Outcome*		
		Begin[a]	*Mode*	*Lifespan increase [%]*	*Neuromuscular function*	*Motor neuron protection*
Riluzole	SOD1 G93A	Early	Oral	11	Not reported	Not reported
	pmn	Early	Oral	<10	Yes	Not reported
Creatine	SOD1 G93A	Early	Oral	18	Yes	Yes
Minocyclin	SOD1 G37R	Early	Oral	≈6	Yes	Yes
Minocyclin+ Riluzole+ Nimodipin	SOD1 G37R	Early	Oral	13	Yes	Yes
zVAD-fmk	SOD1 G93A	Early	Intrathecal	21	Yes	Yes
NT-3 Adeno	*pmn*	Early	i.m.	50	yes	Yes
GDNF AAV	SOD1 G93A	Early	i.m.	14	yes	Yes
CT-1Adeno	SOD1 G93A	Early	i.m	8	yes	Yes
	pmn	Early	i.m.	18	yes	Yes
IGF AAV	SOD1 G93A	Late	i.m.	18	yes	Yes

[a]Treatment begin is classified with respect to disease onset: ''early'' treatments are initiated in the presymptomatic period, ''late'' treatments are started at or after disease onset.

patients have since then taken creatine, but a recent placebo-controlled clinical trial disclosed any beneficial effect of oral creatine at 10 g per day. Encouraging results were obtained by intrathecal infusion of the broad caspase inhibitor zVAD-fmk. Recently, several studies have also reported positive effects of minocyclin, which might be related to the inhibitory actions of this tetracyclin analog on caspase activation, mitochondrial cytochrome c release, cdk5 deregulation, or microglial cell activation. When minocyclin was administered in combination with riluzole and the calcium channel blocker nimodipin, the therapeutic benefit was further enhanced.

Gene therapy strategies have been developed to overcome the side effects of systemically delivered neurotrophic factors. These strategies have been tested since 1992 in *pmn* mice and since 2001 in transgenic mutant SOD1 mice (Table 2). In *pmn* mice, the implantation of genetically engineered tumor cells or subcutaneous implantation of encapsulated fibroblasts secreting CNTF reduced degeneration of phrenic and facial motor neurons. When injected intramuscularly in newborn *pmn* mice, adenovirus vectors encoding the neurotrophic factors NT-3, CNTF, and CT-1 were shown to improve neuromuscular function, reduce motor neuron degeneration, and increase the animal's lifespan. Recently, a nonviral gene transfer method, intramuscular injection and electroporation of plasmid DNA, proved to be as efficient as the adenovirus-based strategy to attenuate disease symptoms.

In transgenic mutant SOD1 mice, adenovirus, AAV, and lentivirus vectors coding for CT-1, GDNF, and more recently IGF-1 and VEGF, administered by intramuscular injection, resulted in therapeutic benefit. Some of these therapies were also capable to slow down motor neuron degeneration when started late, after the onset of

disease. In order to translate these encouraging findings into clinical therapies, a number of fundamental questions now needs to be addressed: Are the observed effects due to release of the neurotrophic factors into the bloodstream or due to retrograde vector transport from muscles to motor neuron cell bodies? What are the best factors, alone or in combination? What is the safest and most efficient vector system?

5.2 Future Concepts

Since motor axons degenerate weeks to months before cell bodies in human ALS and in corresponding mouse models, therapies aimed at axonal protection appear particularly attractive. This concept is further illustrated by studies in the mouse mutant *Wallerian degeneration slow (*Wld^S*, Ola)*: In normal mice, a peripheral nerve lesion leads to axonal disintegration and reactive proliferation of Schwann cells in the distal nerve stump, a process called *Wallerian degeneration*. In Wld^S mice, however, the distal nerve stump remains intact following a lesion and remains able to conduct action potentials during several weeks. The Wld^S mutation was identified as a triplication on chromosome 4 that gives rise to a fusion protein between a truncated ubiquitination factor (Ube4b) and an enzyme involved in NAD synthesis (nicotinamide mononucleotide adenylyltransferase, Nmnat). Interestingly, Wld^S protects axons not only against lesion but also in various other paradigms such as Taxol- and Vincristin-induced neurotoxicity and in the inherited motor neuron disease *pmn*. Because of this broad therapeutic potential, Wld^S and its molecular effectors have become the focus of intense research efforts.

Another innovative approach consists in knocking down the expression of pathological SOD1 alleles by using the RNA interference (RNAi) technique. RNAi has been discovered as a natural gene-silencing mechanism in which double-stranded RNA triggers the degradation of homologous messenger RNAs with extraordinary sequence specificity. The mediators of mRNA degradation are small, 21- to 23-nucleotide long, RNAs (siRNAs). Since almost most ALS-linked SOD1 mutations represent single nucleotide substitutions, it is possible to design RNA sequences that specifically silence mutant SOD1 alleles without affecting expression of the wild-type allele. These RNAs are transfected as double-stranded oligonucleotides into the target cell or expressed as small hairpin RNAs from plasmid DNA vectors or lentiviral vectors. The appropriate target cell and the level of SOD1 gene silencing necessary to achieve therapeutic effects remain to be determined.

6 Conclusions and Perspectives

In the last decade, advances in genetics, molecular and cell biology, and gene therapy have boosted research on motor neuron diseases. Several gene mutations responsible for motor neuron diseases in humans (SOD1, Alsin) and mice (Dynein, Chaperones, etc.) have been identified. These discoveries led to new pathogenic hypotheses, implicating excessive glutamate levels, toxic protein aggregates, mitochondrial damage, or axonal dysfunction. It is becoming clear that multiple disease pathways – triggered in the motor neuron or in neighboring cells – can converge and

cause degeneration. Experimental therapies targeting these pathways at various levels are investigated with increasing success in relevant cellular and animal models. Translating these approaches into clinically relevant therapies represents the major challenge of the future.

Keywords

Amyotrophic Lateral Sclerosis (ALS)
A clinical syndrome defined by degenerative changes of lower and upper motor neurons.

Motor Neuron Disease (MND)
A variety of sporadic and inherited diseases characterized by muscle weakness due to primary degeneration of motor neurons of the spinal cord, brain stem motor nuclei, and populations of central motor neurons.

Neurotrophic Factors
Polypeptide molecules that support the survival of specific populations of neuronal cells, such as spinal motor neurons in culture and *in vivo*, via specific signal-transducing receptors.

Spinal Muscular Atrophy (SMA)
A group of disorders that are characterized by degeneration of lower (spinal and bulbar) motor neurons.

The term ''motor neuron disease'' refers to a variety of devastating neurological disorders characterized by a generalized degeneration of motoneurons. The common clinical manifestations of such disorders are progressive muscle weakness and often death by respiratory failure. Inherited and sporadic forms occur. Further clinical distinctions are made according to the onset of the disorder and whether the disease involves only spinal and bulbar motor neurons (spinal muscular atrophy), or both the lower and upper motor neurons. The most common forms of motor neuron disease are spinal muscular atrophy with an incidence of 1 : 6000 to 10 000 newborns, and sporadic amyotrophic lateral sclerosis with a prevalence of 1 : 100 000, which corresponds to an incidence of 1 : 10 000. About 90% of all cases of amyotrophic lateral sclerosis are sporadic. This disorder affects mostly adults, has a typical clinical appearance, is noninherited, still incurable, and invariably fatal. Recent years have seen the identification of a variety of disease mechanisms, which all lead to the degeneration of motor neurons. Thus, pharmacological approaches that can interfere with degeneration and cell death can now be developed but are complicated by the fact that such therapeutic strategies might work only in subpopulations and not in all patients with this disease.

1 Neuronal Cell Death: Implications for Motoneuron Disease

Motor neurons were among the first populations of neurons that were seen to undergo cell death to a significant extent during development. Such observations, made in the first part of the twentieth century, led to the concept of programmed cell death in the nervous system and to the proposal that target-derived neurotrophic

factors play a key role in the maintenance of motor neuron survival and function during the development and in the adult. In the meantime, a variety of such neurotrophic factors have been characterized on the molecular and functional levels, and genetic analysis of patients with motor neuron disease has revealed that only very few patients show mutations or deletions in the genes for these factors. In such cases, it has been found that mutations in the genes for CNTF (ciliary neurotrophic factor) and LIF (Leukaemia inhibitory factor) might act as modifiers, but not as the cause for the disease. Both in patients and in a mouse model of familial ALS, homozygous inactivation of the CNTF gene leads to earlier disease onset. However, the cause of the disease might lie in other functional defects that are not related to the expression of neurotrophic factors or their effects on motor neurons. Studies with mouse models have shown that overexpression of mutant forms of Superoxide dismutase-I (SOD-I) leads to motor neuron disease and that mutations in genes that are relevant for axonal transport and maintenance of axonal processes seem to be more relevant than mechanisms that regulate survival and/or cell death of the motor neuron cell bodies. This indicates that the cell death of motor neuron cell bodies in motor neuron disease might be a secondary phenomenon that occurs as a consequence of axonal defects. On the other hand, a mouse model in which the gene for bcl-2, a key regulator of cellular survival, has been inactivated shows postnatal degeneration of motor neurons. Moreover, cell culture models have revealed that motor neurons derived from SOD-I transgenic mice are much more sensitive to pro-apoptotic stimuli such as Fas ligand and others. In addition, the induction of cell death after binding of excess glutamate to AMPA receptors is also discussed as a cause of motor neuron cell death in motor neuron disease (MND).

Movement of higher organisms requires nerve cells for coordination. The anatomy and physiology of the motor neurons innervating the skeletal musculature is highly conserved from lower to higher vertebrate species – much more than in other parts of the nervous system that are responsible for higher brain functions which are, for example, defective in Alzheimer's disease and other form of dementia. Thus, motor neurons appear as an ideal subject to study neurodegenerative mechanisms in cell culture models, animal models, and to compare these findings with clinical data.

2 Motor Neurons: Anatomical Aspects

The skeletal musculature is innervated by motor neurons located either in the ventral part (the ventrolateral horn) of the spinal cord or in the brain stem motor nuclei. The cell bodies of these motor neurons reside within the central nervous system, and the axons project into the nerves of the peripheral nervous system to the muscle, which they innervate. Many of these axons reach considerable length. For example, the cell bodies of motor neurons innervating the foot muscles are located in the lumbar spinal cord; thus, the total length of these cells can exceed 1 m in humans. This specific property identifies motor neurons as being among the most highly organized cell types of higher organisms.

The transmitter synthesized by motor neurons and released at the motor end plate, the specific synapses in skeletal

muscle, is acetylcholine. Cholinergic neurotransmission to muscle cells is highly conserved from lower organisms to man.

Spinal motor neurons are in contact with many other cell types, including other neurons, in particular, interneurons of the spinal cord, astrocytes, oligodendrocytes in the central nervous system, and Schwann and muscle cells in the periphery. They receive synaptic inputs both from proprioceptive sensory neurons and from spinal interneurons. These interneurons receive input from upper motor neurons. The upper motor neurons can also project directly to spinal motor neurons. Interneurons in the spinal cord are responsible for spinal reflexes, and also coordinate patterns for coordinated motor neuron innervation, which are responsible for movement. Neurons of the cortical spinal tract (upper motor neurons), projecting to spinal and brain stem motor neurons either directly or via interneurons, are important for voluntary movement. The cell bodies of these upper motor neurons are located in the brain in specific regions of the precentral cortex. These cells are also affected by degenerative changes in various forms of human MND, in particular, in amyotrophic lateral sclerosis (ALS).

3
Clinical Appearance and Pathology

3.1
Inherited forms of MND: the Identification of Gene Defects, Animal Models, and Disease Mechanisms

In the case of inherited MND, more than 50 different forms have been distinguished on the basis of clinical parameters. The underlying gene defects for the major forms of MND in childhood, classical SMA, and spinal muscular atrophy with respiratory distress (SMARD) have been identified, and the gene defects for three out of five forms of familial amyotrophic lateral sclerosis are known. Furthermore, an increased size of a polymorphic triplet (CRG repeat) in the coding region of the androgen receptor gene on the X chromosome has been identified as the cause of X-linked spinal muscular atrophy. This defect leads to progressive muscle weakness and atrophy, as well as to gynecomastia and reduced fertility in affected males. Although only about 10% of adult onset ALS is familial, this group appears to be heterogeneous. The first identified gene defect that accounts for about 10 to 20% of familial ALS are point mutations in the gene for Cu^{2+}/Cn^{2+}-dependent superoxide dismutase (SOD-I). More than 50 different mutations in this gene have been identified most of them leading to autosomal dominant ALS, but there are also mutations in this gene that cause an autosomal recessive form of the disease. Clinically, there seems to be no clear correlation between disease onset or severity with specific mutations in the *SOD-I* gene, suggesting that modifiers exist.

However, some types of mutations in the *SOD-I* gene are prone to cause severe and rapid course of the disease, for example, the A4V mutation, whereas others, that is, E21G, G37R, D90A, G93C, G93V, I104F, L144S, and I151T are generally associated with survival times of more than 10 to 15 years. The D90A mutation is generally inherited as a recessive trait, and this mutation exists also as a polymorphism in the Scandinavian population. There are studies suggesting that about 100 000 heterozygous carriers for the D90A polymorphism exist in Finland alone.

The gene for another autosomal recessive form of ALS, which is coupled to mutations in the Chr2q33 region, has been identified as a mutation in *Alsin2*. This gene encodes for a GTP exchange factor, which resembles other RanGEF or RhoGEF molecules. This finding appears interesting, as such factors appear as the major signal mediators for extracellular regulators of axon growth and possibly also for axon maintenance. The gene for another rare autosomal dominant form of juvenile ALS (ALS 4) has been recently identified on chromosome 9q34 as missense mutation (T3I, L389S, and R2136H) in the senataxin gene. This gene encodes for a protein of more than 300 kD. The function of this protein is still unknown, but it contains a DNA/RNA helicase domain with homology to human IGHMBP2 that has been shown to be mutant in a specific form of spinal muscular atrophy with respiratory distress (SMARD 1). Interestingly, mutations in senataxin lead to an early form of ALS and patients normally fall ill at an age >25 years. This suggests that some forms of SMA and juvenile ALS are pathophysiologically related. Rapid progress is currently made in the identification of other forms of familial ALS.

A major breakthrough in understanding the cause of motor neuron disease in children was the identification of the underlying gene defect in classical SMA. Familial forms of lower motor neuron degeneration are among the most common genetic causes of death in children, leading to muscle weakness and respiratory failure within a few years after birth in the most severe forms. According to their severity, the autosomal inherited disorders are classified as spinal muscular atrophy type I (most severe form, also named Werdnig–Hoffmann disease), type II and type III (Kugelberg–Welander disease). All three forms map to chromosome 5 (5q13). The responsible gene defect for all three forms of SMA type is located in the survival motoneuron (*SMN*1) gene, which is positioned within a duplicated region on human chromosome 5q13. Homozygous mutation or lack of the telomeric *SMN* gene is associated with SMA, whereas mutations within the centromeric copy are not responsible for SMA. The number of centromeric copies of the *SMN* gene varies, and various lines of evidence suggest that the number of centromeric *SMN* copies (*SMN2*) and the levels of *SMN*2 gene expression correlate with the severity of the disease. In general, patients with less severe forms (SMA type III, Kugelberg–Welander) have more copies of the centromeric *SMN*2 gene than patients with type I SMA (Werdnig–Hoffmann's disease).

The *SMN* gene is highly conserved among higher organisms. Orthologous genes have been identified in mouse, *drosophila*, *Caenorhabditis elegans*, and the fission yeast *Schizosaccharomyces pombe*. The *SMN* gene duplication is an event that took place just after the divergence of rodents and primates. In humans, both *SMN* copies differ in that full-length protein is predominantly produced from the telomeric *SMN* gene copy. The expression of the truncated SMN2 protein is caused by a C > T exchange at position +6 in exon 7, which leads to skipping of exon 7 encoded regions in about 70% of the protein product derived from the *SMN*2 gene. This specific gene constellation has not been observed in primates, indicating that differential splicing for exon 7 with consequent development of SMA is restricted to humans. Point mutations in the telomeric *SMN* gene are only observed in 5% of

SMA patients. Hot spots of mutational events are found in exon 6 and the 5′ part of exon 7. These regions code for the *SMN* homodimerization domain.

In the past two years, many efforts have been made both in the identification of SMN-associated proteins and the analysis of cellular functions of SMN and SMN-associated proteins. The *SMN* gene is ubiquitously expressed and encodes for a protein of 294 amino acids, which is found both in the nucleus within specific structures called *gemini of coiled bodies* (gems) and in the cytoplasm, both in the cell body and in axons. A group of interacting proteins, which are colocalized in the nucleus includes gemin-2, gemin-3/gp103, a putative DEAD box RNA helicase, gemin-4, which interacts with gemin-3, but not directly with SMN, profilin, fibrillarin, and spliceosomal U snRNPs of the Sm class. The so-called SMN complex also includes other proteins called gemin-5 – 7. The SMN complex is involved in the biogenesis of spliceosomal U snRNPs. U snRNPs are involved in pre-mRNA splicing in the nucleus. Antibodies raised against gemin-2 and SMN interfere with binding of SMN to U snRNAs. This indicates that the SMN complex is essential for the assembly of U snRNPs. Indeed, gene knockout of *Smn* and *gemin-2* in mice is embryonic lethal at early stages of development before blastocysts implant in the uterus. In contrast to humans, the *SMN* gene is not duplicated in mice.

U snRNP assembly is essential for all types of cells and not only for motor neurons. Therefore, the specificity of a disease process for motor neurons remains obscure. The question of why reduced amounts of ubiquitously expressed SMN protein specifically cause degeneration of motor neurons without affecting other somatic cell types is still not fully answered. One explanation could be that SMN, in addition to its reported function, exhibits motor neuron–specific functions that are not relevant for other cells. It is not clear whether all SMN protein is bound to gemin-2 *in vivo*, and evidence from immunohistochemistry indicates that Smn – but not other proteins of the Smn complex – is enriched in axon terminals. In this specific part of motor neurons, the Smn protein seems associated with the hnRNP R protein. The interaction of SMN with hnRNP R requires the exon 7 encoded domains. A complex of SMN and hnRNP R is associated with the 3′-untranslated region of the β-actin mRNA, and mouse models of SMA, which exhibit reduced levels of Smn protein show reduced accumulation of β-actin mRNA in axon terminals. This correlates with β-actin protein levels in axon terminals and reduced axon growth in cultured motor neurons from Smn-deficient mice. Surprisingly, survival of isolated motor neurons with reduced SMN levels is not altered in comparison to wild-type controls. This indicates that the degeneration of motoneurons in the mouse model for spinal muscular atrophy might be a consequence of axonal defects. Lack of motor neuron function and degeneration of motor endplates and terminal axon also affects the capacity of these motor neurons to take up neurotrophic factors. Retrograde transport of these ligands together with their receptors to the cell bodies is reduced, and this should result in degeneration of motor neurons, which is similar to that in mouse models that lack receptors for neurotrophic factors such as gp130, LIFR-β, or CNTFR-α.

In patients with sporadic motor neuron disease, mutations were identified in the

gene coding for heavy neurofilaments subunit. These mutations lead to alterations in the KSP-region, a domain with lysine-serine-proline-repeats, which is known to form the side-arm structures that cross-link the neurofilaments. This finding is particularly interesting in the light of neurofilaments pathology observed in ALS patients. However, such mutations are rare and only found in about 1% of patients with sporadic ALS.

Mutations were also found in the gene for dynactin, which points to a role by axonal transport in the pathophysiology of MND. Transgenic mice in which individual components of the axonal transport machinery are inactivated show classical signs of motor neuron disease. Also, the identification of the underlying gene defect in the mouse mutant progressive motoneuron disease (pmn) points to the relevance of axonal transport for the pathophysiology of MND. A point mutation in the tubulin-specific chaperone E gene is responsible for the motor neuron disease in this mouse model. Interestingly, disease onset and progression can significantly be modulated by pharmacological treatment with the neurotrophic factor ciliary neurotrophic factor (CNTF). This indicates that the role of neurotrophic factors is not restricted to the promotion of neuronal survival, but extends to axonal maintenance, regulation of microtubule synthesis, and regulation of axonal transport.

Interestingly, the androgen receptor, the Cu^{2+}/Cn^{2+}-dependent superoxide dismutase, and neurofilament genes are widely expressed and little is known about what makes the disease process specific to motor neurons. It can be speculated that generalized disorders might manifest themselves as MND, possibly because motor neurons are more vulnerable or sensitive to any of these defects than other cell types. Moreover, these examples demonstrate that different, unrelated gene defects have a similar clinical appearance resembling typical signs of MND indicating that MND cannot be considered to be a homogeneous disorder.

3.2 Basic Pathological Findings of ALS

As a characteristic feature of ALS (albeit with significant variation from case to case), loss of motor neurons occurs. The remaining cells appear shrunken, dark, with basophilic cytoplasm and pyknosis of the nuclei. Shrinkage of the cells, which precedes neuronal death, occurs in both upper and lower motor neurons. It has been suggested that the degeneration of lower motor neurons is a consequence of the loss of corticobulbar neurons. However, morphometric comparison of the loss of upper and lower motor neurons does not support such hypotheses. The morphological characteristics of motor neuron cell death such as disintegration of the Golgi complex, loss of Nissl structure, shrinkage, any particular pyknosis of the nuclei, very much resemble the changes occurring during apoptosis. However, experimental proof is poor that motor neuron cell death in all forms of MND is apoptotic. Several studies with postmortem ALS spinal cord have identified TUNEL-positive motor neurons. However, it is not clear whether classical apoptotic mechanisms are responsible for cell death, and when they are activated during the course of the disease. In particular, it remains to be demonstrated that apoptotic mechanisms are disturbed at early stages before first symptoms of the disease become clinically apparent.

Increasing evidence suggests that the disease process in ALS, the most common form of MND, might not be limited to

motor neurons. There is also evidence of abnormal rates of degeneration in sensory neurons, but there is little doubt that the motor system is the site of predominant manifestation of the disease. Impairment of axonal transport might underlie many of the pathological characteristics. Inclusion bodies of several types have been described in the perikarya of motor neurons, such as basophilic inclusion, which are thought to consist mainly of RNA, eosinophilic Bunina bodies that resemble autophagosomes, and hyaline-inclusion, originally thought to be characteristic of familial ALS. This points to a role of abnormal protein degradation via the proteasome system, and experimental evidence mainly from cultured neurons suggests that increased proteasome activity can interfere with the pathological mechanisms in some models of MND, such as cell lines overexpressing mutant forms of SOD-I. Hyaline inclusions consist of densely packed phosphorylated neurofilaments, and it is believed that an impairment of slow anterograde axonal transport is responsible for their accumulation in the perikarya of motor neurons. Thus, defects in axonal transport and in protein degradation could play together in the pathophysiology of MND. The concept of impaired axonal maintenance is further supported by the finding that more myelinated nerve fibers are detectable in proximal than in distal parts of motor nerves of ALS patients. Failure of motor neurons to maintain distal structures such as the endplates appears as an early stage in the disease process. Evidence of the degeneration of endplates in early stages of the disease has been derived both from electrophysiological (spontaneous muscle fiber activity) and morphological studies. The disease then progresses to degeneration of the axons in a dying-back fashion, finally leading to degeneration of the cell bodies in the spinal cord and brain stem. Clinical symptoms are expected to become apparent only after it has become impossible to compensate for the loss of functional motor neurons by collateral sprouting and rearrangement of motor units. This coincides with the stage at which motor neuron nerve terminals are affected. Thus, clinical symptoms can precede the degeneration of cell bodies.

4 Sporadic MND: The Pathophysiological Mechanisms Are Still Obscure

The majority of cases (>90%) of MND occur sporadically, precluding the analysis of underlying gene defects by classical molecular genetic analysis. Candidate gene approaches have been conducted in only a few places, and it is premature to state whether the identified mutations may be responsible for the development of the disease in general or only in small subsets of patients. For example, gene defects of heavy neurofilament subunits have been observed only in a few patients (see Sect. 3.1). However, these data do not tell us whether spontaneous gene defects are pathogenic, or whether epigenetic influences (such as intoxication, infection, autoimmune disorders, or any combination of such mechanisms) might be responsible for the disorder. Moreover, defects in the genes coding for neurotrophic factors or their receptors such as CNTF or CNTFR-α have been observed in healthy individuals and in patients with neurological disorders. Targeted disruption of such genes in mice leads to slow degeneration of motor neurons and changes in motor axons in the case of ciliary neurotrophic factor gene knockout. However, symptoms of muscle weakness are only

very mild. Mice with gene defects in the CNTFR-α or LIFR-β gene die around birth and thus cannot be considered as a model for human MND. The severe discrepancy between gene activation of ligands such as CNTF or LIF and for receptor components such as CNTFR-α or LIFR-β suggests that defects in the genes for neurotrophic factors are compensated for by other members of the same gene family. In this case, MND would only occur when such compensatory mechanisms fail or when several kinds of degenerative influences act together, leading to such severe cellular dysfunction of motor neurons that compensatory mechanisms are not sufficient to prevent functional deficits.

There have been suggestions that many pathological mechanisms, some of them listed in Sect. 3, may be responsible for MND, but convincing evidence that interference with any of them results in an effective treatment of MND is still lacking. The only effective drug currently used for treatment of MND, Riluzole, interferes with a variety of mechanisms including glutamate toxicity, function of ion channels, and possibly additional intracellular signaling pathways, which modulate the function and structural maintenance of motor neurons. The conclusion that can be drawn from this situation is that basic mechanisms of MND are far from being understood.

4.1 The Autoimmune Hypothesis of Motoneuron Disease

There are many reports of abnormal immunological findings in MND patients. One of the most intriguing is the toxicity of serum from ALS patients to cultures of isolated motor neurons. Moreover, abnormalities in the composition of subgroups of peripheral blood lymphocyte subsets have been described; for example, there is a decrease in mature T lymphocytes (CD3-positive cells) and a shift in the CD4/CD8-ratio in favor of CD8-positive cells, as well as an increase in natural killer cells (CD57 and CD16 positive cells). However, these findings have not been confirmed by recent studies. Another line of evidence has been derived from studies searching for autoantibodies directed at nerve antigens. Such studies have revealed antibodies against gangliosides (GM1), acetylcholine esterase, and L-type or P-type Ca^{2+}-channels. Such findings are in apparent contrast to many unsuccessful efforts to treat ALS by immunosuppressive strategies. Even total body lymph node irradiation was without effect. Some patients with high titers of anti-GM1-antibodies diagnosed as ALS exhibit peripheral nerve multifocal conduction block and are now considered to reflect a subgroup of chronic multifocal inflammatory neuropathy rather than degenerative MND. It now appears conceivable that in the course of MND epitopes on motor neurons that usually are hidden to the immune system become exposed, they allow secondary autoimmune mechanisms to come into play and add to the degenerative changes in motor neurons. Even if autoimmune mechanisms are not primary events, they could contribute to the clinical picture of MND by accelerating the functional impairment of the remaining motor neurons.

4.2 Toxic Lesions of Motor Neurons

Intoxication with ingredients of cycad plants is thought to be responsible for the ALS-Parkinsonism-dementia complex found in Chamorro populations in the

Western Pacific Islands. Since, however, the disease has been reported to occur up to several decades after exposure to the toxic agents, it is not clear whether the intoxication itself is responsible for the disease or whether it induces a long-lasting increase in the vulnerability of motor neurons to other agents. It has been suggested that *β-N*-methylamino-L-alanine (LBMAA) or the increased concentrations of glutamate and abnormal excitatory amino acids detectable in the cerebrospinal fluid of ALS patients could induce motor neuron degeneration via glutamate receptors. Glutamate toxicity via *N*-methyl-D-aspartate (NMDA) receptors is a common degenerative mechanism in other disorders of the nervous system such as stroke and CNS-trauma. However, clinical trials with NMDA-receptor antagonists such as dextromethorphan have not shown efficiency in ALS patients. However, there is evidence *in vitro* that AMPA receptors, in particular, Ca^{2+} influx through this receptor, are responsible for glutamate toxicity in motor neurons. EAAT2 variant transcripts have been found in the brain of ALS patients in combination with reduced EAAT2 protein levels. This is thought to cause elevated glutamate levels at the synapses that are located on the dendrites of bulbar and spinal motor neurons. Further evidence of glutamate toxicity in ALS is based on the efficacy of Riluzole, the only available drug for treatment of ALS up to now. This drug candidate is thought to act as a presynaptic inhibitor of glutamate release, but there is also evidence for other mechanisms of action. The role of glutamate toxicity in motor neurons has also been demonstrated after viral infection. Neuroadapted Sindbis virus mediates motor neuron death indirectly via an excitotoxic mechanism involving glutamate and calcium-permeable AMPA receptors.

5
Oxidative Stress: Is Motoneuron Degeneration in Familial ALS Due to Loss or Gain of Function of the Enzyme Superoxide Dismutase?

Mutations within the Cu/Zn-dependent superoxide dismutase (*SOD-I*) gene on chromosome 21 in about 2 to 5% of ALS patients has led to reinvestigations of all the observations and speculations that oxidative damage may play a pathogenic role in MND. SOD-I had already been the focus of interest in the context of the Alzheimer-like neurodegenerative changes associated with Down Syndrome. In the search for genes responsible for degenerative changes, patients with partial duplication of chromosome 21 translocated to other chromosomes were analyzed, and the 21q22 region has been found to be critical. Among the roughly 100 genes encoded in this region, the *SOD-I* gene was considered to be a good candidate, the duplication and consequent overexpression of which might be responsible for the degenerative changes observed in Down Syndrome: Indeed, overexpression of SOD-I in neural cell lines results in impaired neurotransmitter metabolism.

To obtain information on a possible role of increased SOD-I activity in neurodegenerative processes in more detail, transgenic mice overexpressing the human *SOD-I* gene under its homologous promoter were produced. These transgenic mice show pathological changes in motor neurons, such as withdrawal and destruction of terminal axons at the neuromuscular endplates and development of multiple small terminals in comparison to normal age-matched mice. Surprisingly, gene knockout of the *SOD-I* gene did not lead to MND, indicating that this enzyme is dispensable for maintenance of motor

neurons, and its function is probably fully compensated by other enzymes such as SOD-II.

In the meantime, more than 60 mutations have been reported in patients with autosomal dominant ALS (ALS-1). These are widely scattered over the gene with hot spots in exon 4 and 5. Mutations of the conserved glycine at position 93 are quite abundant, and the A4V mutation, which is in particular found in North American families, generally leads to a severe course of ALS. The D90A mutation is quite abundant in Sweden and Finland, and in contrast to the other mutations, it is inherited as a recessive trait. 1 to 2% of the population in Scandinavia is heterozygous for the D90A allele. In Finland, about 100 000 persons are estimated to be carriers of this mutation. In general, patients with the D90A homozygous mutation show a relatively mild form of ALS with an average survival time of more than 10 years. Surprisingly, the age of onset does not differ from very severe forms such as the A4V form, indicating that other factors determine the age of onset, which act independently from those that determine survival time. Enzyme activity of SOD-I is only reduced by about 50% in most patients with familial ALS, as expected for autosomal dominant inheritance, leaving one allele of the *SOD-I* gene intact. It was suggested that the mutations lead to decreased enzyme activity either by causing an allosteric effect on the active center of the enzyme or by interfering with the formation of dimers, which is the form in which the enzyme naturally occurs in cells.

Mice with transgenic overexpression of mutant SOD-I generally show protein aggregates and other alterations in motor neurons, which become clearly detectable when the disease is clinically apparent. However, it is not fully understood whether such aggregates are responsible for the disease. Alternatively, it has been suggested that the inability of mutant SOD-I to bind copper might lead to accumulation of protein complexes and toxicity of free copper in cells and thus to neurodegeneration. Acquisition of copper by SOD-I requires a specific copper chaperone, a member of the family of metallochaperones, which regulate intracellular trafficking of metal ions. However, inactivation of this chaperone in each of the three most frequently used mouse models for ALS indicates that the disease is unaffected by elimination of copper loading. This argues against the possibility that primary toxicity arises from aberrant copper within the neurons. Morphological changes in mitochondria within motor neurons were observed as an early feature both in SOD-I^{G37R} and SOD-I^{G93A}–transgenic mice. This correlates with reduced mitochondrial function at least in SOD-I^{G93A}. Interestingly, mutant SOD-I^{G93A} has been detected within spinal cord mitochondria, and recent studies have shown that the accumulation of mutant SOD-I in mitochondria is also found in other ALS-linked mutations, and that these changes lead to damage of mitochondria-bound proteins. Therefore, it has been suggested that motor neuron–specific damage of mitochondria might be the reason for the selective toxicity of mutant SOD-I in MND.

6 Disintegration of Axonal Transport: Implications for MND

Several mouse mutants have been identified or generated in which disturbance of components of the cytoskeleton, of microtubuli, or of components of the axonal transport machinery lead to typical signs

of MND. Recently, missense point mutations in the cytoplasmic dynein heavy chain have been identified as the cause for motor neuron disease in *Loa*- and *CIra1*-mutant mice. Dynein is part of the motor complex for protein and vesicle movement along microtubules in the minus-end direction and thus an important component for retrograde axonal transport. Interestingly, the defect does not only lead to reduced retrograde transport but also to progressive postnatal loss of motor neurons. Whereas motor neuron loss is not detectable at an age of 3 months, about 50% of the motor neurons are lost at 16 to 19 months. Mutations in the p150 subunit of the transporter protein dynactin have been identified in a family with autosomal dominant progressive MND. Dynactin binds both to microtubules and to dynein, and thus acts as an essential component of the axonal transport machinery, which mediates binding of transport vesicle and transport proteins to microtubules. Mice in which dynamitin, the p50 inhibitory subunit of the dynactin complex, is overexpressed also show late onset MND.

Other widely used mouse models are *Pmn* mice, which develop a rapidly progressive form of MND between the third and fifth postnatal weeks. Histologically, the mice exhibit atrophy and loss of motor axons and at a later stage loss of motor neuron cell bodies in the spinal cord and brain stem motor nuclei. In addition, neurons in the red nucleus degenerate. The axonal projections from this nucleus to the spinal motor neurons – the corticospinal tract – are functionally linked to the corticospinal tract in rodents and contribute significantly to the innervation of spinal motor neurons. It thus functionally resembles the upper motor neuron input to lower motor neurons in higher vertebrates. As the cause of the disease, a single amino acid exchange in the most C-terminal part of the tubulin-specific chaperone E (TBCE) protein was identified. The resulting protein appears less stable, but it could also be that translocation of the protein to axons, the function of the protein or interactions with other functionally relevant proteins are affected. These hypotheses need additional experimental data.

In summary, these data suggest that axonal transport plays an essential role in motor neuron maintenance, and future research on the pathophysiology of MND in humans will focus on the question whether defects in axonal transport are an early or late phenomenon in the disease.

The cytoskeleton of most animal cells contains a variety of elements also including thin actin filaments and intermediate filaments in addition to the microtubules. The β-actin mRNA is one among a small population of mRNAs, which are axonally transported. The functional relevance of axonal transport has been a point of debate for a long time. In contrast to dendritic transport, it has been argued that it is not clear whether the translocalized mRNAs are translated within the axonal compartment. Axonal transport of β-actin mRNA has been studied in much detail. A specific 3′-UTR region called *zip code* has been identified within β-actin mRNA that confers axonal localization. Proteins that bind to the zip-code region of β-actin mRNA have been named zip-code binding protein 1 (ZBP1) and ZBP2. It has been found that the formation of a particle involving β-actin mRNA and ZBP1 is necessary for β-actin translocation to growth cones. The translocation of the mRNA is increased by neurotrophic factors such as neurotrophin-3. In motoneurons, axonal terminals contain polyribosomes, which can be detected with specific antibodies against large subunit ribosomal RNA or

by electron microscopy. The SMN protein, which is deficient in spinal muscular atrophy, binds to hnRNP R in the axonal compartment, and it has been shown that a complex of SMN and hnRNP R also interacts with the zip-code domain of β-actin mRNA. Motor neurons that lack Smn show reduced accumulation of β-actin mRNA in axon terminals. This correlates with highly reduced levels of β-actin protein in the axon terminals and reduced axon growth of isolated motor neurons in cell culture. In contrast, overexpression of SMN and/or hnRNP R in neuronal cell lines enhances neurite outgrowth, thus indicating that the translocation of β-actin mRNA and the local translation of this protein in axon terminals play a major role in axon growth and maintenance. Also in other animal models such as zebrafish, knockdown of SMN primarily leads to axonal disturbance and not to motor neuron cell death. Thus, spinal muscular atrophy might be considered as a disease that is caused by defective axonal translocation of β-actin mRNA. It will be interesting to know whether similar mechanisms also account for subtypes of adult onset MND. First indications have been obtained by the identification of mutations in senataxin, a protein with a DNA-helicase domain that is mutated in a rare form of inherited amyotrophic lateral sclerosis.

7 Identification of Neurotrophic Factors and Cytokines that can Regulate Survival and Function of Motor Neurons

Survival of embryonic spinal motor neurons depends on neurotrophic factors obtained from skeletal muscle and glial cells. Such factors are taken up by motor neurons by means of specific receptors and transported to motor neuron cell bodies where they act on specific parameters. In this way, these factors regulate apoptosis, transmitter synthesis, and other aspects of motor neuron function. Developing embryos and cultured embryonic spinal motor neurons have been used to identify neurotrophic factors and cytokines capable of supporting the survival of developing motor neurons. Positive effects have been observed for members of the ciliary neurotrophic factor (CNTF) family, for brain-derived neurotrophic factor (BDNF), neurotrophin (NT)-3 and -4, insulin-like growth factor (IGF) and members of the glial-derived neurotrophic factor (GDNF) family. These factors differ in their tissue distribution and temporal expression patterns, and gene knockout experiments have indicated that their modes of action might overlap with other members of the same gene family and probably of others. Interestingly, neurotrophic factors can interfere with the pathophysiology of motor neuron disease caused by different mechanisms. Positive effects are observed with IGF-I in mice that overexpress SOD-I. Pmn mutant mice show improved survival and motor performance after treatment with CNTF. This indicates that these factors can interfere with distinct pathophysiological mechanisms that have been identified for MND. The molecular mechanisms of these actions appear to be important for development of therapy and could lead the way to the identification of new small molecules that are active on the same targets.

8 Future Prospects for Treatment of MND

A large number of clinical trials with a variety of drugs and therapeutic strategies

have been carried out in the past in the search for an effective treatment of MND. Among them were plasmapheresis (with the intention of removing toxic or autoaggressive molecules), drugs such as corticosteroids, corticotropin, cyclosporine A, and cyclophosphamide, which are known to be effective in autoimmune diseases. None of these trials were successful. Similar negative effects were observed in trials with growth hormone and thyrotropin-releasing factor.

A driving force behind some of the current therapeutic trials for the treatment of MND is the assumption that degeneration of motor neurons might be caused by mechanisms similar to those responsible for the death of other neurons of the central nervous system after glutamate exposure. Therefore, considerable attention has focused on clinical trials with glutamate antagonists and glutamate release inhibitors such as Riluzole and other drugs. Trials with free radical scavengers such as acetylcysteine, which are thought to reduce the generation of free radicals, a pathomechanism that has been implicated by mutations in the *SOD-I* gene in familial ALS, have not been successful so far.

Clinical trials with neurotrophic factors such as CNTF and BDNF have also failed. Among many potential reasons are, in particular, adverse pharmacokinetics. Thus, the factors are not available to the motor neuron cell bodies residing in the spinal cord. Alternatively, it could be that the receptors desensitize within a short time to neurotrophic factors, so that only short-time effects occur, which are not sufficient for a therapeutic effect of these drug candidates. Indeed, even promising trials with mouse models such as *Pmn* mice or SOD-I transgenic mice generally focus on treatment periods of only a few weeks, whereas treatment of patients would require positive drug effects over several years. Nevertheless, the positive effects of IGF-I, BDNF, and CNTF in various mouse models of motor neuron disease are a good basis for further research and the development of new therapeutic strategies that might help promote long-term effects in the degenerating motor neuron.

Another problem that needs to be solved is the apparent heterogeneity of pathomechanisms, in particular in familial and probably also sporadic ALS. It could well be that drug candidates that interfere with some pathomechanisms are without any effect in patients suffering from MND due to another defect. Therefore, the genetic and molecular basis of disease needs to be better understood, and techniques for genotyping and molecular diagnosis have to be developed so that the pathomechanism of MND can be characterized for individual patients, even in patients with sporadic ALS. Potential positive or negative effects for the various drug candidates can only be tested on this basis.

This problem seems to be easier for patients with various forms of spinal muscular atrophy. The molecular basis of classical autosomal recessive SMA, which is caused by a mutation of the *SMN* gene, is known and can be easily tested and characterized. Thus, prerequisites exist to develop drugs on a rational basis. The same is also true for other forms of childhood spinal muscular atrophy such as SMARD and for adult onset X-linked spinal muscular atrophy (Kennedy's disease), which is caused by a polyglutamine-expansion in the androgen receptor gene. Multiple lines of evidence indicate that this mutation leads to a gain of pathogenic function, which requires the translocation of the receptor after binding of testosterone. Thus, anti-androgens

have been suggested as drug candidates, and first trials with candidates such as leuprorelin showed promising results by reversing the behavioral and histopathological phenotypes in a mouse model. It is to be expected that clinical trials based on such results will be initiated soon, and new drug candidates will be developed with cell culture and mouse models, which can be developed once the molecular and genetic basis of the disease is known.

Keywords

Allostery
Pertaining to or involving a change in conformation caused by the attachment of a ligand or substrate.

Mechanoenzyme
A catalytic enzyme that produces motion and force.

Processivity
A measure of the number of catalytic cycles an enzyme undergoes before detaching from the substrate. In the context of motors, processivity is proportional to the average distance over which the enzyme translocates on its filamentous substrate before detaching.

Substrate
A molecule on which an enzyme acts. In the context of molecular motors, either the fuel source (e.g. NTPs), or the force-generating partner (e.g. actin filament).

Working Stroke
A conformational change that occurs during a single round of catalysis, and which drives motion and force production. The working stroke length, or working distance, is the maximal distance associated with the stroke. The working distance can be different from the distance between consecutive attachment sites on the partner filament.

Cellular motions have fascinated biologists during the 400 years since the invention of the optical microscope first allowed them to be seen. Today, we know that motions underlying the most essential processes of life – such as cell division, energy transduction, muscle contraction, DNA replication, transcription, and translation – are generated by molecular motors. A molecular motor is a protein, or a complex of proteins and nucleic acids, that produces motion and force. For fuel,

many molecular motors consume nucleotide triphosphates, breaking an energy-rich phosphate bond to release chemical energy, and then converting this into mechanical work. Other motors tap electrochemical gradients that exist across membranes within bacteria, mitochondria, and chloroplasts. Motor proteins are Nature's nanomachines, and they often function with efficiency that far exceeds the best human-engineered machines.

1 Introduction

Producing motion and force is the primary role of the ''classic'' molecular motors, myosin, kinesin, and dynein. These *mechanoenzymes* all hydrolyze ATP as a source of energy and drive motion along protein filaments. Myosin generates motion along filamentous actin, and is well known for its role in muscle contraction. The seemingly simple act of flexing ones arm requires $\sim 10^{17}$ myosins working together to slide $\sim 10^{15}$ actin filaments toward one another. Kinesin and dynein move along microtubule filaments. An essential role of kinesin is to haul vesicles across neurons. This can be a 6-day haul since the longest neurons are more than a meter, and vesicle transport proceeds at only $2\,\mu m\,s^{-1}$. Dynein causes the beating of flagella and cilia, such as those lining the lungs, by sliding microtubules past one another.

Besides the classic motors, there are many ''nontraditional'' motor proteins. In some cases, motion and force production are byproducts rather than a primary function. The main role of DNA and RNA polymerases is to copy and transcribe the genetic code. In order to do so, they move along their nucleic acid templates, sometimes with amazing endurance. A single RNA polymerase molecule can transcribe all 2.5 million bases of the human dystrophin gene in 14 h, at roughly 50 bases per second. Another nontraditional motor is F_1F_0-ATP synthase, which is responsible for replenishing the entire pool of ATP in all cells using energy derived from metabolism. As this enzyme toils, it also spins – it is a rotary motor. A flow of protons causes a shaft within the motor to rotate continuously, and shaft rotation is then coupled to the synthesis of ATP from ADP and phosphate. A third type of nontraditional motor activity is driven by the cytoskeletal polymers, actin, and tubulin. In addition to their roles as structural cables and girders for maintaining cell shape, and as highways for motor proteins to move along, these polymers are themselves dynamic machines that produce force. The leading edges of macrophages and other crawling cells are pushed outward by polymerizing actin filaments. Microtubule depolymerization generates tension that pulls chromosomes apart prior to cell division.

This chapter is a survey of the main classes of molecular motors. It begins with a discussion of the classic mechanoenzymes, myosin, kinesin, and dynein. These motors have been the subject of biophysical research for decades, and our understanding of their function serves as a foundation for the study of other motors. The chapter then turns to nontraditional motors, focusing on a handful of key examples, including nucleic acid enzymes (RNA polymerase), rotary motors

(F_1F_0-ATP synthase, and the bacterial flagellar motor), and protein polymers (actin and tubulin). A central goal of research on motor proteins is to determine how underlying biochemical events, such as ATP hydrolysis, are coupled to mechanical action. Progress toward this goal is chronicled throughout the chapter through description of experiments with classic and nontraditional motors.

2 Classic Molecular Motors

Myosin, kinesin, and dynein are founding members of large families of proteins whose primary function is to generate motion and force. Owing to their structural resemblance, the motors of each family operate in a manner similar to the founding proteins. However, they drive a wide variety of different cellular motions beyond the stereotypical roles of muscle contraction, vesicle transport, and the beating of cilia. There are at least 15 classes of myosin (traditionally denoted with roman numerals I through XV), and only a handful are involved in muscle contraction. Some of the other types are implicated in vesicle budding, cytokinesis, and organelle transport along actin cables. Likewise, kinesin-like proteins and cytoplasmic dyneins are essential for the formation and positioning of the mitotic spindle, chromosome separation prior to cell division, and organelle

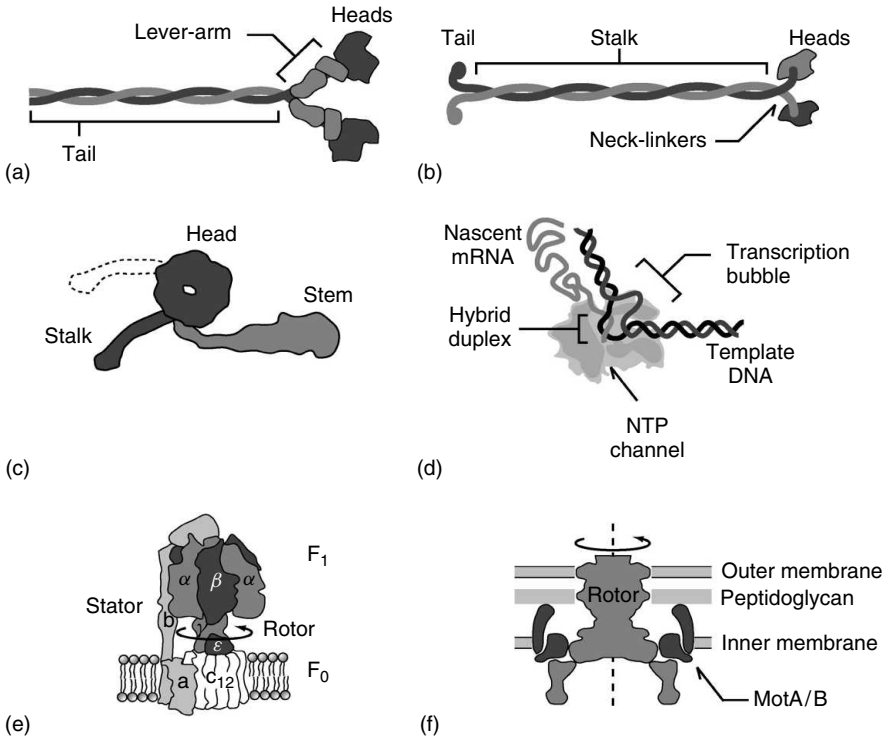
Fig. 1 Structures of some classic and nontraditional molecular motors. (a) Muscle myosin consists of two heads connected to a common coiled-coil tail. The heads bind actin and carry ATP hydrolysis activity. A rodlike portion of each head (light gray) functions as a lever-arm, tilting $\sim 70^\circ$ relative to the remainder of the head (dark gray) upon attachment to an actin filament. The tail promotes bundling of myosin molecules into thick filaments. (b) Kinesin also has two heads, connected through short polypeptides called *neck linkers* to a common coiled-coil stalk. The heads bind microtubules and carry ATP hydrolysis activity. A conformational change of the neck linkers may drive kinesin motion. The tail binds cargo. (c) Each dynein molecule consists of a donut-shaped head with two rodlike structures, the stem and stalk, emanating from the head. The head contains four ATP-binding sites, only one of which is catalytically active. The tip of the stalk binds microtubules. To drive motion, the head and stalk rotate relative to the stem, which attaches to cargo and can also bundle two or three dynein heads together. (d) RNAP is shaped like a claw, which opens to allow a DNA template to enter, and then wraps completely around the DNA during transcription. While transcribing, RNAP separates a portion of the DNA duplex called the *transcription bubble*, and maintains registration of a short section of hybrid RNA:DNA duplex. Nucleotides enter through a channel, leading to the active site, where they are incorporated into the nascent mRNA chain. (e) F_1F_0-ATP synthase consists of two rotary motors, connected to a common shaft, which act as a motor-generator pair. The F_0 portion taps a proton gradient across the inner mitochondrial membrane to drive spinning of the rotor (c_{12}) relative to the stator (ab_2). The F_1 portion sits directly above F_0, and contains a shaft ($\gamma\varepsilon$) that is rigidly fixed to the rotor of F_0, and also a ring $(\alpha\beta)_3$ that is rigidly fixed to the stator of F_0. Spinning of the shaft relative to the ring drives ATP synthesis. The isolated F_1 portion is known as F_1-ATPase because in the presence of ATP it will spin in reverse, catalyzing ATP hydrolysis. (e) Cross-sectional view of the rotary motor of bacterial flagella. The motor core contains a stack of rings (rotor), embedded in the multilayered cell wall that rotates as a single unit about an axis (dashed line) perpendicular to the surface of the bacteria. Rotation is driven by torque-generating units composed of MotA and MotB proteins. The MotA/B complex is anchored to fixed structures (peptidoglycan) within the cell wall. Protons flow through a channel within MotA/B, where protonation and deprotonation of MotB induces conformational changes in MotA, which attaches and detaches from the base of the rotor and drives its rotation.

movement along microtubules. The discussion here centers on the founding proteins, their functional properties, and some of the experiments that uncovered these properties. Particular attention is given to *in vitro* work with single motor molecules.

2.1 Muscle Myosin: Tilting Cross-bridges Drive Contraction

The motor activity of myosin was discovered more than 50 years ago. Electron microscopy revealed that muscle fibers consist of parallel thick and thin filaments that slide past one another during contraction. Tiny structures termed "cross-bridges," connecting laterally between the filaments, were suspected to drive filament sliding. In some images, the cross-bridges projected from the thick filaments at right angles, but in others, they were tilted, depending on tissue preparation conditions. These observations led to the theory, now well established, that cross-bridges drive filament sliding by cyclically attaching to the thin filaments, tilting, detaching, and untilting.

The thick filaments are now known to be bundles of myosin molecules. Each myosin consists of two identical 200-kDa polypeptides, plus two pairs of light chains (20 kDa). The heavy chains fold into twin globular heads connected to a common coiled-coil tail (Fig. 1a). Two light chains bind each head near the head–tail junction. Myosins bundle together by their long tails, and their heads project from the bundles, forming the cross-bridges that drive



filament sliding. The heads can bind and hydrolyze ATP, and also carry a site that attaches to actin, the main component of the thin filaments, with ATP-dependent affinity. In high-resolution structures, a rodlike portion of the myosin head is found in several different orientations relative to the remainder of the head. Tilting of this "lever-arm," not the entire head, probably drives filament sliding.

The thin filaments of muscle are composed mainly of actin. Actin is a roughly spherical protein that polymerizes into a ropelike structure, with two strands, called *protofilaments*, that twist around one another. The filaments are polar, with a "plus" or "barbed" end, and a "minus" or "pointed" end, which are structurally different. During muscle contraction, the thick filaments slide toward the plus ends of the thin filaments.

2.2 Seeing is Believing: Motility Assays Demonstrate Motor Activity

A wealth of biochemical and structural information supports the tilting cross-bridge model of muscle contraction. However, the most compelling evidence for myosin motility comes from direct observation of motion generated *in vitro*. Myosin and actin are too small to see in an optical microscope. So, *in vitro* motility assays depend on various labeling schemes to render the motion visible. In the earliest assays, micron-sized beads were coated with myosin, and the beads were then observed to move along actin cables in the cytoplasm of the alga *Nitella*, and later along purified actin filaments bound to a glass surface. In an alternate strategy, actin filaments were made visible by fluorescent labeling, and gliding of these labeled filaments on myosin-coated glass surfaces was observed in a fluorescence microscope (Fig. 2a). These important experiments established beyond doubt that actin and myosin alone, without any additional components from muscle cells, were sufficient to generate motion and force. Consistent with the rotating cross-bridge theory, ATP was required for the motility, and the myosins moved toward the plus ends of the actin filaments. Filaments glided *in vitro* at 6000 nm s^{-1} (Table 1), similar to the speed at which thick and thin filaments slide past one another during muscle contraction. As discussed below, these two basic tests – the "bead assay" and the "gliding filament assay" – have been adapted and refined to study a variety of other motors in addition to myosin (Fig. 2b through d).

2.3 Kinesin: Intracellular Porter

Motility assays were instrumental in the discovery of kinesin. Observations of the squid giant axon suggested the existence of motors that consume ATP and haul vesicles at speeds of 1 to 2 μm s^{-1} along the dense array of microtubule filaments within the axon. A putative motor was first isolated by locking the vesicles onto the microtubules using a nonhydrolyzable ATP analog, AMPPNP, followed by purification of the microtubules, and then release of the motor with ATP. A gliding filament assay identical to that developed for myosin confirmed that the purified protein, kinesin, was indeed a motor: glass surfaces coated with kinesin supported the ATP-dependent gliding of microtubules. The gliding velocity, 800 nm s^{-1} (Table 1), closely matched the speed of vesicle transport.

Additional assays, using microtubules marked to reveal their intrinsic polarity, revealed the direction of kinesin-driven

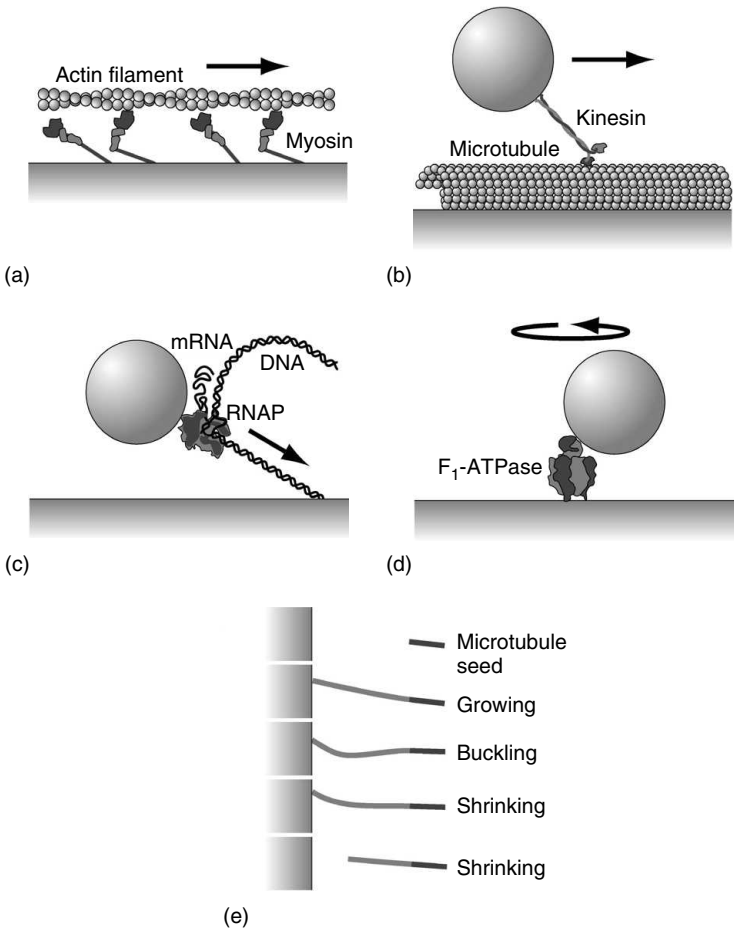


Fig. 2 Motility assays adapted for various molecular motors. (a) In the gliding filament assay, coverslip-bound motors drive filaments to move in a direction parallel to the filament long axis. Here, many myosin heads are shown interacting with a single actin filament. (b) In the bead motility assay, motors are attached to microscopic glass or plastic beads, which are pulled by the motors along coverslip-bound filaments. Kinesin is shown moving along a microtubule. (c) The tethered particle assay was developed to study the motion of nucleic acid enzymes along DNA filaments. Here, a microscopic bead is attached to RNA polymerase, which is transcribing a DNA filament that is attached at one end to the coverslip. Transcription results in a shortening (or lengthening) of the tether (depending on which end of the DNA is surface-bound). (d) In the rotation assay for F_1-ATPase, the motor is attached to a coverslip, and the orientation of the shaft is marked by off-axis attachment of a microscopic bead or filament. Spinning of the shaft causes the bead or filament to rotate. (e) Force generation by polymerization has been demonstrated by growing dynamic microtubule extensions from coverslip-bound seeds. The microtubules continue to elongate even after their growing ends encounter a barricade, which generates enough compressive force to buckle the filaments.

Tab. 1 Properties of selected molecular motors.

Protein Machine	*Molecular Weight (kDa)*	*Force-generating Partner*	*Energy Source*	*Maximum Speed (nm s^{-1})*[a]	*Maximum Force (pN)*[a]	*Step Size (nm)*[a]	*Processivity (cycles)*
Kinesin, native heterotetramer	340	Microtubule	ATP	1800

Actin filament, growing	40 (G-actin monomer)	n/a	Binding	~15			n/a

[a]Different units apply to the rotary motors, F_1F_0-ATP synthase, F_1-ATPase, and the bacterial flagellar motor. For these, the maximum rotation rate, torque, and angular step size are reported in units of Hz, pN nm, and degrees, as noted.

motion. Microtubules are rigid, tube-shaped polymers, composed of tubulin proteins arranged in a lattice, resembling a miniature drinking straw. Like actin filaments, microtubules have two structurally distinct ends, called ''plus'' and ''minus''. Polarity-marked filaments driven by kinesin glided with their minus ends leading, implying that kinesin was moving toward the plus ends.

Kinesin and myosin share many structural and functional similarities. Like myosin, each kinesin molecule consists of two identical polypeptides that form twin heads connected to a common coiled-coil stalk (Fig. 1b). The motor activity is carried by the heads. Each head hydrolyzes ATP and attaches to microtubule filaments with nucleotide-dependent affinity. But unlike myosin, the tail of kinesin does not cause bundling, it binds the motor to its cargo. Furthermore, atomic structures of kinesin heads are devoid of any rodlike structure resembling the lever-arm of myosin. Lacking a lever, kinesin's working stroke is likely to be very different from that of myosin.

2.4 Ciliary Dynein: The Dark Horse

Comparatively little functional information is available for the third classic motor, dynein, even though its activity was discovered around the same time as that of myosin. Electron micrographs revealed lateral connections between the parallel microtubules in cilia and flagella, similar to the myosin cross-bridges in muscle. The cross-bridges in cilia and flagella are dynein motors that drive bending motions by sliding microtubules past one another.

Dynein is larger and structurally more complex than kinesin or myosin, but it has many features common to all the classic motors. Depending on the source, dynein consists of one, two, or three large (500 kDa) polypeptides. Each of these forms a donut-shaped head, with two rodlike structures emanating from it, the ''stem'' and the ''stalk'' (Fig. 1c). The stem functions similar to the tails of kinesin and myosin, bundling the heads together, and also anchoring them tightly to their cargo. The tip of the stalk binds microtubules in an ATP-dependent manner, like the microtubule binding site within each of kinesin's heads. No atomic resolution structures are available for dynein, but electron microscopy of single dynein particles revealed a conformational change akin to the lever-arm tilting of myosin: under different nucleotide conditions, the stem adopts two different orientations relative to the head and stalk. Thus, dynein may move its stem-bound cargo by cyclically attaching via the stalk to a microtubule, rotating the stalk and head, detaching from the microtubule, and then unrotating. Dynein supports microtubule gliding and bead motion in *in vitro* assays. The direction of dynein-driven motion is toward the minus end of the microtubule, opposite that of kinesin-driven motion.

Dynein's complex structure contains a number of features with unknown functional significance. Dynein motors from different sources have different numbers of heads. Each donut-shaped head consists of six different subdomains arranged in a hexameric ring. Four of these subdomains bind ATP, but only one catalyzes hydrolysis. Nucleotide binding, but not hydrolysis, at one of the other subdomains is essential for motor activity. Uncovering the reasons for this complexity and elucidating dynein's mechanism of action are important frontiers for future research.

2.5 Processivity Allows Kinesin to Work Alone

Soon after its discovery, kinesin was found to possess a tenacity that set it apart from myosin and dynein. Kinesin is highly *processive*, staying attached to the microtubule as it undergoes many catalytic cycles, and translocating over relatively long distances before detaching. This processivity was first demonstrated when gliding filaments or moving beads were found to move long distances (1–2 μm), even when the surface density of motors on the slide or bead was extremely low, ensuring that single kinesin–microtubule interactions were very likely. Several independent lines of evidence now provide very strong evidence of kinesin's processivity (see Fig. 3).

The processivity of kinesin probably evolved as a means to conserve cellular resources. Kinesin's role of transporting vesicles across neurons is a critical task that must be accomplished repeatedly and with high reliability in order for these cells to function. The longest neurons contain millions of vesicles that each take weeks to make the journey from one end to the other. Kinesin's high processivity allows this Herculean task to be completed by just a few motors bound to each vesicle. In principle, the job could also be accomplished by nonprocessive motors, but many more motors would be required. The cell, in turn, would have to devote more energy and resources into producing these additional molecules.

Apart from its biological significance, kinesin's processivity has been a great advantage for experimentalists, allowing the first studies of single motor molecules. Motility assays for myosin relied on hundreds of motors acting together because the tiny tilting motions, or *working strokes*, of the individual heads are too small to see in a conventional optical microscope. However, owing to their high degree of processivity, kinesins generate hundreds of working strokes during each encounter with a microtubule moving distances of ~1 μm. The summation of many strokes renders the motion of individual kinesin motors easily visible.

Results from single molecule motility assays revealed a number of insights about how kinesin moves. The motion of kinesin-driven beads *in vitro* was not random over the microtubule surface, but appeared to follow a path parallel to the protofilaments. Gliding filament assays supplied strong evidence for protofilament tracking, when abnormal microtubules with helical protofilaments were shown to rotate about their long axis as they moved. In bead assays, engineered kinesin proteins with only one head failed to generate highly processive motion, indicating that two heads are, in fact, better than one.

2.6 Rowers Versus Porters: Duty Ratio Makes a Difference

The head domains of myosin and kinesin differ markedly in their duty ratio, the fraction of time during each biochemical cycle that they remain attached to their partner filament. Myosin possesses a low duty ratio that allows groups of molecules to work together efficiently, like the rowers of a large canoe, while kinesin has a high ratio, befitting its role as a lone porter. A myosin head has high affinity for actin just after hydrolysis, when the nucleotide-binding pocket contains either ADP and phosphate, or ADP alone, and low affinity when the pocket is empty or contains ATP. The timing of transitions between these states ensures that the high-affinity

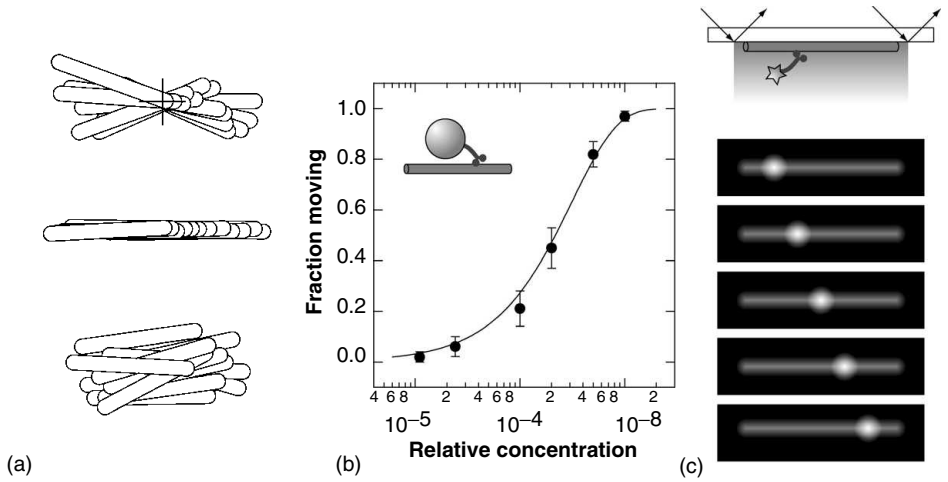

Fig. 3 Strong evidence for the processivity of kinesin. The first evidence for processivity was that kinesin-driven motion persisted *in vitro* even when the surface density of motors was extremely low. (a) Nodal point pivoting in the gliding filament assay also indicated processivity. Microtubules gliding on surfaces decorated sparsely with kinesin rotated erratically about a fixed location, even as they moved through this nodal point. When the trailing end of the microtubule reached the nodal point, it dissociated from the surface and diffused back into solution. A single motor at the nodal point presumably drove the motion (top). Negligible rotation occurred at high motor densities, when multiple motor–filament interactions constrained the filament orientation (middle). Both types of motion were distinct from thermal motion of free filaments in the absence of motor (bottom). [Adapted from Howard, J., Hudspeth, A.J., Vale, R.D. (1989) Movement of microtubules by single kinesin molecules, *Nature* **342**, 154–158.] (b) In the kinesin bead assay, the fraction of moving beads, f, decreased gradually as the relative motor concentration, C, was lowered, as expected if one molecule is sufficient to produce movement. The curve shows a one parameter (λ) fit to Poisson statistics, $f = 1 - \exp(-\lambda C)$. [Adapted from Svoboda, K., Block, S.M. (1994) Force and velocity measured for single kinesin molecules, *Cell* **77**, 773–784.] In the low-density regime, moving beads continued to translocate at normal speeds over distances that were independent of motor concentration (data not shown). (c) A third method used a microscope capable of imaging single fluorophores bound to kinesin (upper panel). The movement of labeled motors along coverslip-bound filaments was directly observed (shown schematically in the lower five panels). [Adapted from Vale, R.D., Funatsu, T., Pierce, D.W., Romberg, L., Harada, Y., Yanagida, T. (1996) Direct observation of single kinesin molecules moving along microtubules, *Nature* **380**, 451–453.] Labeling the motor by fusion to green fluorescent protein avoided chemical modification with reactive dyes, which can damage the motors, and ensured that every motor was labeled with the same number of fluorophores.

states represent <2% of the total cycle time. This low duty ratio is an adaptation that allows the myosin heads to avoid interfering with each other when many are acting on the same actin filament. They detach very quickly after undergoing a working stroke, so the speed of filament sliding is not limited by the hydrolysis rate of the individual heads. In contrast, kinesin heads have a duty ratio >50%, which partially explains the processivity of the motor. Even if the cycles of the two heads were completely uncorrelated, their high duty ratio would ensure that, on

average, at least one was always bound to the microtubule.

2.7 Molecular Tug-of-war: Applying Force to Individual Motors

With the development of single molecule assays, it became possible to directly measure the forces generated by individual motors. One method for measuring force production by kinesin was to attach a microtubule filament to a flexible glass fiber, and then hold the fiber near a surface sparsely coated with kinesin. As individual kinesins on the surface bound and moved along the microtubule, they pulled against the glass fiber and caused it to bend. By measuring the amount of bending, the maximum force against which a kinesin motor could move was estimated to be 5 or 6 pN.

Another method for applying force to individual kinesin molecules, which gave a similar estimate of the stall force and also led to a number of other discoveries, was to use an optical trap. An optical trap is made by focusing a laser through the objective lens of a high-magnification microscope, creating a very bright light spot at the specimen. The focused light traps small objects such as micron-sized beads. When the trapped object is moved away from the center of focus, it feels a restoring force pulling it back that is proportional to the distance from the center, as if the trap was a stretched spring pulling on the object. To apply force to kinesin, an optical trap was used to grab beads with single kinesin molecules attached, and to place them near microtubules stuck onto to a glass surface. When the kinesin began moving along the microtubule, it pulled the bead from the trap center, and the trap supplied a restoring force that placed tension on the kinesin. As the bead was pulled gradually away from the trap center, the force increased and the motor speed decreased, halting when the force reached 6 pN.

2.8 Motors Move in Discrete Steps

Kinesin molecules move discontinuously over the microtubule surface, advancing in discrete 8-nm increments and dwelling at well-defined positions between advancements (Fig. 4). Two key innovations allowed the first observation of steps in the motion of kinesin-driven beads. First, tension supplied by an optical trap suppressed the random, thermally driven (''Brownian'') motion that would otherwise dominate. Second, the bead position was measured with very high spatial and temporal resolution by monitoring the distribution of scattered light with a photodetector. The 8-nm step size (Fig. 4b) matches the spacing of tubulin dimers in the microtubule lattice. Similar experiments with dynein, which is processive under some conditions, suggest that it also moves stepwise, advancing by multiples of 8 nm.

Optical trapping has been applied to measure the motion of single myosin motors. A different technique than that used for kinesin was required because the interactions between a myosin molecule and an actin filament are fleeting, lasting only a few tens of milliseconds. To resolve these quick attachments, an assay was developed in which an actin filament with beads attached at both ends was suspended between two optical traps and held near a surface sparsely coated with myosin (Fig. 4c). Thermal motion of the beads decreased when a motor became attached to the filament, and the average position of the beads shifted abruptly, due to the tilting of the myosin head, by 6 nm. This tiny

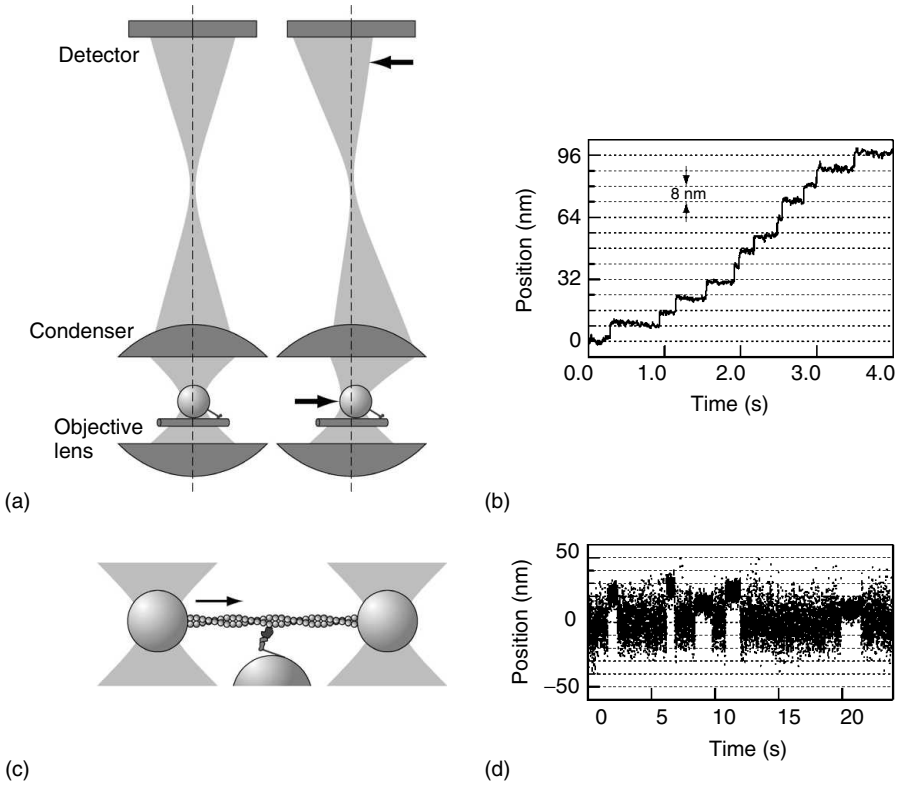

Fig. 4 Measuring the discrete motions of kinesin and myosin molecules using optical traps. Both methods use microscopic beads as handles to apply force, and as markers for the position of the motor or filament. (a) An optical trap applies tension during kinesin-driven movement of a bead along a coverslip-bound microtubule, and this tension reduces thermal motion of the bead so that individual 8-nm steps can be resolved. Bead position is detected with very high spatial resolution by monitoring the distribution of scattered light with a photodetector. (b) Example trace showing 8-nm steps generated by a single kinesin molecule. (c) The three-bead assay developed for measuring working strokes of muscle myosin. An actin filament is pulled taut between two microscopic beads held in optical traps. Binding of a single myosin head to the filament reduces thermal motion of the beads, and also induces a working stroke in the myosin, which causes the beads to deflect by 5 to 15 nm. (d) Example trace showing interactions between a single myosin head and an actin filament. [Data reprinted with permission from Lister, I., Schmitz, S., Walker, M., Trinick, J., Buss, F., Veigel, C., Kendrick-Jones, J. (2004) A monomeric myosin VI with a large working stroke, *EMBO J.* **23**, 1729–1738.]

distance is the maximum sliding distance that a myosin molecule can generate during a single interaction with actin during muscle contraction. More than a million of these interactions are evidently required just to lift a finger.

2.9 Different Strokes: Variation Within and Across Motor Families

In accordance with their diverse roles, motors of the myosin, kinesin, and dynein

families often have important differences in the way they move. The cellular role of type V myosin, for example, is more similar to that of kinesin than to muscle myosin. Myosin V acts alone or in small numbers to transport vesicles and organelles along actin cables. It was therefore not surprising to find that this myosin, like kinesin, exhibits processive movement, taking several steps along an actin filament before detaching. The step size of myosin V, 36 nm, is much larger than that of kinesin, and matches the wide spacing of binding sites that occur every half-period in the actin helix. The structure of myosin V explains how it can generate such large movements. Each head contains a lever-arm that is 24 nm long, three times longer than the lever-arm of muscle myosin.

Diversity within motor families invites comparison, which can illuminate important aspects of motor function. Strong evidence supporting the tilting lever-arm model came from comparisons of gliding speeds and stroke lengths generated *in vitro* by myosin-family motors with different lever-arm lengths. The speeds and stroke lengths varied in proportion with the lever-arm length, as predicted by the model. Structural differences between kinesin and Ncd, a related motor that moves toward the opposite end of microtubules, suggested that a ''gearbox'' region just outside the head domain controls the direction of motion of these motors. This hypothesis was confirmed by testing chimeric motors, made by swapping the gearbox regions of the two proteins, in gliding filament assays.

2.10
Fuel Economy and Energy Efficiency

How many ATP molecules does a motor require to generate a working stroke or step? Is this ''fuel economy'' always the same? For kinesin, the coupling ratio – the number of ATPs consumed per step – has been measured by comparing the stepping rate in single molecule assays to the rate of ATP hydrolysis. Over a wide range of ATP concentrations and loads, one ATP is hydrolyzed per 8-nm step. This tight, 1 : 1 coupling implies that the energy efficiency of kinesin can be very high. ATP hydrolysis under physiological conditions is worth $\sim$80 pN nm (or $2{\cdot}10^{-23}$ kcal). When kinesin generates 8-nm steps under 5 pN of load, it produces as much as 40 pN nm (10^{-23} kcal), or 50% of the total chemical energy available. So kinesin is more than twice as efficient as the best man-made gasoline engines, which are 24% efficient at full power, and typically achieve only 10 to 15% on the road.

The energy efficiency of cytoplasmic dynein, 10%, is considerably lower than that of kinesin. However, dynein's complex structure may act like an automobile transmission, allowing it to maximize fuel economy. Near dynein's stall force, 1 pN, the motor takes 8-nm steps. At $<$0.4 pN, however, it seems to advance in larger increments of 24 or 32 nm. Thus, dynein can apparently shift into high gear when carrying a light load. Assuming that the coupling ratio under both conditions is equal, the larger step size will result in proportionally better fuel economy.

2.11
Walk This Way: Processive Mechanoenzymes Move Hand-over-hand

The fact that single kinesin molecules generate hundreds of steps, even under load, together with the earlier findings of motion parallel to the protofilaments and

the requirement for two heads, suggested that it might walk – or waddle – from one tubulin dimer to the next. An attractive hypothesis was that the twin heads each take turns, alternately detaching and moving past one another, in a ''hand-over-hand'' motion resembling that of a person swinging along monkey bars. The same model was also thought to apply to the processive myosin-family motor, myosin V.

Single molecule experiments with myosin V and kinesin have confirmed that both walk hand-over-hand. First, the stride length of myosin V was measured by labeling one of its two heads with a fluorophore, and tracking the label with nanometer resolution. This is like watching a person walking across a field on a moonless night with a flashlight attached to one foot: The person is invisible, but the light moves visibly with every other step. The heads of myosin V took turns making strides that were twice as long as the distance moved by the tail, evidence that strongly supported a hand-over-hand model. Next, optical trapping experiments showed that some kinesin molecules limp along the microtubule, exhibiting a difference in the timing of every other step. Limping implied that kinesin switched between two different configurations as it stepped. The most severe limpers were mutants in which one head hydrolyzed ATP more slowly than the other, arguing for a mechanism in which the two heads swap both mechanical and catalytic activities with each step. Finally, the stride length for one of kinesin's two heads was measured to be 16 nm, double the step size. Taken together, these results make a very strong case for a hand-over-hand mechanism for kinesin and myosin V.

2.12 Coordination is Required

To fully account for the hand-over-hand walking of kinesin and myosin V, coordination between the two heads is essential, and it may be achieved through mechanical tension between the heads. The mechanical cycle of both motors includes a transient state in which both heads are attached to the filament. The motors are probably stretched in this doubly attached state, owing to the relatively large distance between the heads, and the resulting intermolecular strain between the heads could bias their kinetics so that the trailing head nearly always detaches before the leading head. In support of this hypothesis, external loads have been shown to strongly affect the rate of detachment of single myosin V heads, with forward loads accelerating detachment and backward loads slowing detachment.

Coordinated action at distinct sites is a universal requirement for all motors, not just those with high processivity. Automobile engines rely on the carefully timed actions of pistons, valves, and spark plugs. Mechanoenzymes also have critical interacting parts. Consider the mechanochemical cycle of myosin: Within a few milliseconds after attachment of a myosin head to actin, small motions occur in the nucleotide-binding pocket, allowing phosphate release. This triggers lever-arm tilting, which moves the actin filament. Subsequent ADP release triggers a second, smaller motion in certain myosin types (e.g. myosin I and single myosin V heads), but it is not clear if this additional stroke occurs for muscle myosin. ATP binding triggers detachment from actin, and hydrolysis ''primes'' the motor for the next cycle. For other motors, the specifics and timing are different than for myosin,

but this coordinated action is a universal requirement.

2.13 The Kinesin Cycle and Working Stroke

The mechanochemical cycle of kinesin is not as thoroughly understood as that of myosin. Because two heads are involved in the stepping process, the kinesin cycle is necessarily more complex than that of muscle myosin. The specific conformational changes driving motion are poorly defined, and there is uncertainty about which biochemical events are associated with motion. A working hypothesis for kinesin is that all the mechanical action is associated with just one biochemical event. In support of this ''one-stroke'' hypothesis, reaction schemes with just one force-dependent rate can account for force-velocity and [ATP]-velocity curves measured in single molecule assays. These schemes predict a working stroke after ATP binding, possibly upon ATP hydrolysis. By contrast, a working stroke concomitant with ATP binding is suggested by kinetic measurements, showing that ADP release from one head is stimulated by binding of a nonhydrolyzable ATP analog (e.g. AMPPNP) to the other head.

A conformational change in the structure of kinesin has been discovered that may drive its motion. This putative working stroke is quite different from either the tilting lever-arm of myosin, or the stem reorientation of dynein. In single-headed kinesin constructs, a 15-amino acid peptide known as the ''neck linker,'' which connects each kinesin head to the coiled-coil stalk, undergoes a nucleotide-dependent transition. In the presence of ADP, or when no nucleotide is present, the neck linker is disordered. In this state, it acts like a flexible tether, pivoting about a point on the backside of the head. When the head is attached to a microtubule in the presence of ATP analogs (AMPPNP, ADP-AlF_4^-), the neck linker ''zips'' onto to the surface of the head, and its end points toward the microtubule plus end. In the full two-headed motor, zipping of the neck linker on one head could drive stepping by moving the stalk, and therefore the other head, toward the next attachment site on the microtubule lattice.

2.14 Under the Hood, Motors are Still a Mystery

Even for the best-understood motors, where high-resolution structures are available, and major mechanical steps can be identified with specific biochemical transitions, there are very fundamental questions that remain unanswered. In particular, the atomic-scale motions that transduce small chemical events in the nucleotide pocket and convert them into larger motions elsewhere are poorly understood. Important residues have been identified by comparing sequences of related motors and their precursors (e.g. myosin, kinesin, and G-proteins), and subdomains that move relative to others have been suggested by structural comparison. However, ultimately, these static structures cannot elucidate the timing of movements and the cause-and-effect relationships between the various parts. A myriad of physical and biological techniques will no doubt be essential in this effort, but single molecule techniques that simultaneously record motion and biochemical changes (e.g. through fluorescence) seem particularly valuable in this regard.

3
Nontraditional Molecular Motors

There are many other protein machines that generate force and motion, but which do not fit the classic motor paradigm. A growing number are being studied using *in vitro* assays, like those discussed above, which allow the mechanical output of single motors to be measured.

3.1
Nucleic Acid Enzymes

Some of the most important processes of life are carried out by nucleic acid enzymes, many of which are processive motors that move along DNA. Every human cell stores genetic information in the form of 23 strands of DNA, totaling three billion base pairs, and measuring 1 m in total length. All 23 strands are copied by DNA polymerase enzymes, untangled by topoisomerase enzymes, and packaged into chromosomes by condensins, before cell division. The genetic information contained in the DNA is transcribed into mRNA by RNA polymerase (RNAP), and translated into protein by the ribosome. Each of these nucleic acid enzymes is a protein machine capable of generating force and motion, and each is fascinating in its own right. A discussion of all of them is beyond the scope of this chapter, which will focus on one important example, RNAP.

3.2
More Than a Motor: Multitasking by RNA Polymerase

Even though the size of an RNAP enzyme, by comparison of total molecular weight, is not so different from that of the classic mechanoenzymes, its function is much more complex. Motion is merely a by-product of the biological role of this protein machine, transcribing the genetic code. While moving along a DNA template, RNAP separates a short section of the DNA duplex, the ''transcription bubble,'' and builds a copy of one strand by selecting complementary nucleotides from the surrounding solution and attaching them, one at a time, to the end of the nascent mRNA chain (Fig. 1d). Along the way, it must maintain registration of a short section of ''hybrid'' RNA:DNA duplex, and also respond to a number of different signals that control the initiation, termination, and elongation rate of transcription. Like other mechanoenzymes, RNAP derives energy from nucleotide hydrolysis, but, in this case, each nucleotide serves a dual role. After hydrolysis, the nucleotide becomes an information-containing subunit incorporated into the growing mRNA. (If automobile engines could make such efficient use of their exhaust, urban air quality would be much improved!)

Motion may not be its primary function, but RNAP is no slouch of a motor. Its motion can be directly observed by attaching a micron-sized bead, and recording bead motion as the enzyme transcribes a DNA template bound at one end to a glass surface (Fig. 2c). Using this ''tethered particle'' assay in conjunction with optical trapping, the motion of a single RNAP can be tracked with high spatial resolution, and the effect of applied load can be measured. RNAP is slow, moving in these assays at 10 to 15 bp s^{-1}, or just 5 nm s^{-1} (Table 1). This speed is roughly equivalent to the rate of human hair growth, and 160-fold slower than the speed of kinesin. However, RNAP is much more processive than kinesin. In cells, RNAP molecules synthesize mRNA chains of 10^4 (in

bacteria) to 10^6 (in mammals) nucleotides. *In vitro*, its processivity is reduced, but the enzyme typically moves across several thousand bases or more before detaching from the template. Movement continues, unhindered at 10 to 15 bp s^{-1}, even when backward loads as high as 27 pN are applied. A high stall force (>5-fold higher than that of kinesin) may be necessary for RNAP to function *in vivo*, perhaps allowing the enzyme to push through ''road-blocks'' formed by other DNA-binding proteins. RNAP is presumed to move in discrete steps corresponding to the distance between individual bases along the DNA helix, 0.34 nm. This distance is extraordinarily small (20 times smaller than kinesin's 8-nm steps), and steps of this size have not yet been directly observed. However, optical trapping technology is rapidly advancing, and such tiny motions may soon be resolvable.

3.3 RNA Polymerase Structure

RNAP is shaped like a claw. The claw opens to allow a DNA strand to enter, and during transcription it closes, wrapping completely around the DNA. Besides the DNA entry and exit channels, there is also a channel through which the newly synthesized RNA exits, and a pore for nucleotide entry (Fig. 1d). Inside the closed structure, the enzyme makes numerous contacts with the hybrid duplex and the DNA. It is unknown, which parts of RNAP are responsible for generating motion and force production, but many candidate features are apparent in the high-resolution structures. For example, a ''bridge helix'' located near the site of nucleotide addition may undergo a conformational change that pushes the enzyme to the next site. Determining which portions of RNAP are responsible for its motion is a great challenge for future research.

3.4 What Causes Pauses?

The motion of RNAP along the DNA template is interrupted by pauses, lasting from a few seconds to many minutes. The short-duration pauses (those with lifetimes of seconds) are very frequent, and may result from the enzyme encountering a few GC-rich base pairs of DNA that are tougher-than-average to separate. Occasionally, the enzyme pauses for a much longer duration (20 s to >30 min). These infrequent but long-lived pauses may occur for two reasons, both of which illustrate the sophisticated behavior that RNAP is capable of. First, long pauses can be induced when RNAP encounters a specific sequence in the DNA template it is transcribing. Such sequence-dependent pauses are an important mechanism for regulation of gene expression. By relieving these long pauses, a cell can greatly alter the rate of expression of a pause-containing gene. In some cases, these sequence-dependent pauses occur when the nascent mRNA chain folds into a hairpin structure, which then interacts directly with the RNAP enzyme. In other cases, these pauses occur when the RNAP transcribes a slippery AT-rich sequence, resulting in an unstable RNA:DNA hybrid duplex that allows the enzyme to backtrack. There is a second class of long-duration pauses that are not sequence-dependent, and these probably occur when the enzyme makes a copying error, misincorporating a noncomplementary nucleotide into the mRNA chain. These pauses are also associated with backtracking, and may reflect a

"proofreading" activity whereby the enzyme slides backward and then (with the help of accessory factors) cleaves a short section from the end of the mRNA, removing the mistake before resuming elongation. Determining the reasons why RNAP pauses is critical for understanding how gene transcription is controlled. Single molecule experiments will be useful in this effort because the motion of unsynchronized molecules can be followed with very high resolution, in real time.

3.5 ATP Synthase

A rotary machine, F_1F_0-ATP synthase, is at the heart of energy metabolism in plants, animals, and photosynthetic bacteria, where its role is to replenish the cellular store of ATP. The importance of this job is obvious when one considers that a human body contains 100 g of ATP (0.25 moles), each molecule of which gets hydrolyzed 400 times a day to power various cellular tasks. An army of ATP synthase enzymes performs the $\sim 10^{26}$ synthesis reactions required to regenerate the spent ATP. To do so, the enzymes tap into an electrochemical gradient, the protonmotive force, that exists across the inner mitochondrial membrane of animal cells, or across the thylakoid and plasma membranes of plants and eubacteria, respectively.

ATP synthase consists of two separate rotary motors, F_0 and F_1, that work together as a motor–generator pair. Normally, F_0 is the driving motor of the pair. As protons flow through it, down the electrochemical gradient, a portion of F_0 spins like a water wheel. The spinning wheel of F_0 supplies torque that rotates a shaft within the other motor, F_1, causing it to regenerate ATP from ADP and phosphate. The motor–generator pair can also operate in reverse. In this case, ATP hydrolysis by the F_1 motor causes the shaft to rotate backward, which supplies a torque that spins the wheel of F_0 and pumps protons back up the electrochemical gradient.

F_1F_0-ATP synthase is comprised of eight different types of protein subunits (Fig. 1e). The water wheel, or "rotor" portion of F_0 is a ring of 12 identical subunits, c_{12}, that spin in the plane of the membrane relative to a "stator" composed of three other subunits, ab_2. F_1, is a donut-shaped structure made of three pairs of proteins, $(\alpha\beta)_3$, plus two additional proteins, γ and ε, which form the shaft that fits into the center of the donut. Clockwise (CW) rotation of the $\gamma\varepsilon$ shaft (as seen from the F_0 or membrane side) causes ATP synthesis to occur sequentially at three catalytic sites located symmetrically around the $(\alpha\beta)_3$ ring. Because isolated F_1 can function in reverse, catalyzing ATP hydrolysis and counter clockwise (CCW) rotation of the shaft, it is often referred to as F_1-ATPase. In the full, F_1F_0-ATP synthase enzyme, F_1 sits directly above F_0, with the $\gamma\varepsilon$ shaft of F_1 making a rigid connection to the c_{12} ring of F_0, and with the ab_2 stator of F_0 connecting to the $(\alpha\beta)_3$ donut of F_1. Normally, spinning of c_{12} drives rotation of $\gamma\varepsilon$ within $(\alpha\beta)_3$ and hence ATP synthesis.

The ring-shaped structures within F_1F_0-ATP synthase provided the first clues that rotation might be important to its function. As for the classic mechanoenzymes, proof of motion came when an *in vitro* assay was developed, allowing the rotation to be directly observed. F_1-ATPase molecules were attached sparsely to a surface, and the orientations of their $\gamma\varepsilon$ shafts were marked by attaching micron-long, fluorescent-labeled actin filaments. In the presence of ATP, the filaments rotated CCW, indicating shaft rotation. At very

low concentrations of ATP, the filaments rotated in discrete steps, dwelling at well-defined orientations in between rapid, 120° reorientations. Rotation rates were one-third of the rate of ATP hydrolysis, implying that each 120° reorientation corresponds to hydrolysis of a single ATP. The filaments used to mark shaft orientation also supplied a drag force acting against the rotation. By calculating the drag on the filaments, F_1 was estimated to deliver 40 pN nm of torque during each 120° reorientation, giving 80 pN nm of mechanical work output per ATP hydrolysis. This is 100% of the available chemical energy, making F_1-ATPase one of the most efficient motors known.

F_1-ATPase is a relative newcomer to the molecular motor scene, but it is quickly becoming one of the best-understood examples of mechanochemical coupling. A series of experiments with single F_1 molecules has revealed that each 120° step occurs in two phases, or substeps, that correspond to particular biochemical transitions in the ATP synthesis reactions occurring at each of the three catalytic sites. Substeps were observed by marking the shaft orientation with 40-nm gold particles (Fig. 2d), rather than the much larger filaments used in earlier work. The small beads resulted in a lower drag force acting on the motor, allowing full speed rotation at 160 revolutions per second (Hz) (Table 1). Capturing the motion with a high-speed video camera showed a substep of 80 to 90° followed by one of 30 to 40°, underlying each of the 120° steps previously observed. Finally, simultaneous observation of shaft orientation and binding and release of a fluorescent nucleotide allowed these biochemical steps to be temporally correlated with the substeps. ATP binding to one of the catalytic sites (site 0) is concurrent with the 80 to 90° substep, and the remaining 30 to 40° substep requires hydrolysis at the site that previously bound ATP (site −1), and release of ADP from the remaining site (−2).

It is unknown whether the events seen during ATP hydrolysis by F_1 are simply the reverse of those occurring during synthesis, but several experiments confirm, at least, that the $\gamma\varepsilon$ shaft rotates in the opposite direction during synthesis. In one experiment, magnetic beads attached to the shaft were used to drive CW rotation in F_1-ATPase, in the presence of ADP and phosphate, and a luciferin–luciferase system that emits a photon upon reacting with ATP was used to verify synthesis. In another experiment, individual, fluorescent-labeled F_1F_0-ATP synthase complexes were embedded in liposomes. A pH difference was created across the membrane by rapid dilution, and rotation was recorded by fluorescence resonance energy transfer (FRET).

3.6 The Rotary Motor of Bacterial Flagella

Bacterial flagella are very different from the flagella and cilia of eukaryotic cells. Flagellated bacteria, such as *Escherichia coli*, swim by rotating a set of four corkscrew-shaped filaments (four, on average) that extend from the cell surface out into the surrounding medium. At the base of each filament is a large protein machine that drives filament rotation. This rotary motor, like F_1F_0-ATP synthase, is powered by the protonmotive force, but it is much larger and structurally more complex than F_1F_0-ATP synthase.

Bacteria swim to find food. They control their swimming behavior by altering the direction of rotation of their flagellar motors. When all four motors rotate CCW

(as seen by an observer outside the cell), the cell swims steadily, or ''runs,'' in a relatively straight line parallel to its long axis. When one or more motors rotates CW, the cell ''tumbles,'' erratically moving in place and reorienting itself. The motors switch from CCW to CW at random, so that typical swimming involves runs that last ~1 s, interspersed with tumbles that last a few milliseconds. When the bacteria senses rising nutrient concentrations, it lengthens the runs by increasing the probability of CCW rotation. In this way, the cell moves, on average, toward the food.

The core of the bacterial flagellar motor is a stack of ring-shaped structures, 45 nm in diameter, embedded in the multilayered cell envelope (see Fig 1f). The rings are composed of 20 different types of proteins, but they are all thought to rotate together as a single unit, the ''rotor.'' Rotation of the stack of rings is driven by a circular array of $\leq$16 ''studs'' that surround the base of the stack, and which are anchored to the framework of the cell wall. Each stud is composed of two MotA proteins (32 kDa), and one MotB protein (34 kDa). No high-resolution structures are available for the MotA/MotB complex, but both proteins span the cytoplasmic membrane, forming a transmembrane proton channel. MotB has a proton-acceptor site, and MotA contains a site that interacts with the base of the rotor. Protonation and deprotonation of MotB is thought to cause conformational changes in MotA, which probably binds and unbinds from the rotor, driving rotation and torque generation. The minimal torque-generating unit may be composed of two studs (i.e. four MotA subunits plus two MotB subunits). More detailed descriptions of the structure can be found in review articles cited in the bibliography.

Individual flagellar motors can be studied by attaching bacteria to a glass surface by one flagellum. The tail wags the dog in this tethered cell assay – with the flagellum anchored, rotation of the motor causes the whole cell body to spin. To spin the entire cell, the motor must overcome a large viscous drag, so it spins relatively slowly in this assay, at 10 Hz. But it produces an impressive 4600 pN nm of torque. When mutant cells lacking MotB are tethered, they are paralyzed and do not spin. Amazingly, these paralyzed cells can be ''resurrected'' by expression of MotB from an inducible gene. Resurrected cells begin to rotate within several minutes after induction of MotB expression, and their speed increases in a series of discrete jumps. Each jump in speed represents the incorporation of one additional torque-generating unit into the motor. As many as eight jumps can be seen, implying that the maximum number of torque generators is eight.

Each torque generator is itself a processive, high-duty ratio motor that moves along the surface of the rotor without detaching. The best evidence for processivity is that tethered cells in the resurrection experiment with just one torque-generating unit spin relatively smoothly, and do not freely undergo rotational Brownian motion. Evidently, a single unit is sufficient to prevent the motor from slipping, and each unit remains attached to the rotor during most, or all, of its mechanical cycle. There are twice as many studs (16) as torque-generating units (8), and one hypothesis is that each unit is a coordinated pair of studs, possibly moving in a hand-over-hand motion like that of

kinesin or myosin V. A single unit is expected to move stepwise over the surface of the rotor, perhaps taking ~26 steps per revolution (the approximate number of subunits composing the base of the rotor), but such steps have not been directly observed. Dividing the maximum torque (4600 pN) by the number of torque-generating units (8), and by their distance from the axis of rotation (20 nm), shows that each unit generates considerable force, up to 29 pN, which is comparable to the stall force of RNAP. Their speed of motion over the rotor surface is also quite high. When the viscous load is minimal, the motor can rotate as fast as 300 Hz (Table 1). This translates into motion of the torque-generators at 38 000 nm s^{-1} over the rotor surface, which is >6-fold faster than muscle myosin, and similar to the speed of the fastest myosins (e.g. type XI, responsible for cytoplasmic streaming in algae).

The speed of rotation is proportional to the protonmotive force, as shown by wiring a cell to an external voltage source and watching an inert marker on the motor. To apply voltage, the cell body was drawn halfway into a micropipette, and the membrane permeabilized by chemical treatment. Estimates of the proton flux through the motor suggest that the motor is tightly coupled. Roughly 1200 protons flow through the motor during each complete revolution. By attaching a variety of different-sized latex beads to the filaments and adjusting the viscosity of the surrounding fluid, torque-speed relations have been measured over a wide range of speeds. Forward rotation under assisting torques, and backward rotation under torques above stall (>4600 pN), has been explored by using rotating electric fields or optical traps to apply torque in the tethered cell assay.

3.7 Polymers that Push and Pull

Actin filaments and microtubules are not just static polymers. In addition to their roles as structural cables and girders for maintaining cell shape, and as superhighways for mechanoenzymes to move along, these polymers are also dynamic machines that can produce force. In living cells, the cytoskeletal polymers are in a constant state of flux, and their growth and shrinkage is harnessed to drive many organelle and whole-cell movements. Crawling cells have a dense array of polymerizing actin filaments beneath their leading edge that pushes outward on the plasma membrane and causes protrusion. Similarly, the bacterial pathogen, *Listeria monocytogenes* is pushed by actin polymerization. The bacteria move in graceful arcs through the cytoplasm of a host cell, leaving ''comet tails'' of polymerized actin in their wake. During mitosis, chromosomes are pushed and pulled by dynamic microtubules whose ends are linked to specialized sites on the chromosomes, the kinetochores. Just before cell division, kinetochore-attached microtubules depolymerize, generating tension that pulls sister chromatids apart.

Both actin and microtubule filaments are composed of protein subunits arranged in a regular lattice. The monomeric form of actin, ''G-actin,'' is a roughly spherical protein, 5 nm in diameter (45 kDa). Like a LEGO block, the surface of an actin monomer has several sites for attachment to other monomers. Each also has a cleft that binds an ATP molecule. Monomers assemble into a ropelike structure, ''F-actin,'' with two strands, called *protofilaments*, that wind around each other with a helical period of 72 nm. The building blocks for microtubules are made

of tubulin, a molecule that consists of two nearly identical 50-kDa proteins fused tightly to form a dimer, 8 nm in length. Each dimer has two sites that bind GTP. The dimers assemble into a hollow, tube-shaped structure, 25 nm in diameter, with 13 protofilaments that run parallel to the long axis of the tube. Both types of filaments have fast-growing ''plus'' ends, and slow-growing ''minus'' ends.

Nucleotide hydrolysis supplies energy that makes actin and tubulin polymers very dynamic. Actin monomers in solution bind ATP, and have high affinity for one another. After polymerization, the ATP is hydrolyzed and phosphate is released, leaving ADP trapped in the binding clefts of the monomers within a filament. The ADP-containing monomers have reduced affinity, so hydrolysis destabilizes the actin filament, promoting depolymerization. GTP hydrolysis by tubulin has a similar effect. Each tubulin dimer binds two molecules of GTP, one of which is hydrolyzed upon incorporation of the dimer into a microtubule filament. The GDP-containing tubulin dimers have reduced affinity for one another, which destabilizes the lattice and promotes depolymerization. Without hydrolysis, both polymers would simply grow until equilibrium was reached, when the subunit pool was spent. Hydrolysis keeps the filaments out of equilibrium, allowing coexistence of growing and depolymerizing filaments.

3.8 Microtubule Ends and Dynamic Instability

The dynamic behavior of microtubules can be directly observed *in vitro*. In the presence of GTP and pure tubulin, microtubule growth is interrupted by periods of rapid depolymerization. This ''dynamic instability'' requires GTP hydrolysis. Growth rates are normal in the presence of the nonhydrolyzable GTP analog, GMPCPP, but the growth is uninterrupted. Subunit addition and removal occurs only at the ends of the filaments, which adopt different structures, depending on whether they are in a state of growth or depolymerization. The protofilaments that extend from growing ends are straight, forming sheets that are sometimes hundreds of subunits long. In contrast, the protofilaments at depolymerizing ends become highly curved, peeling away from the lattice. The ends of growing filaments are temporarily stabilized by a ''cap'' of GTP-containing subunits in which hydrolysis has not yet taken place. The transition between growth and depolymerization, called ''catastrophe,'' is probably triggered when hydrolysis of the cap occurs before more GTP-containing subunits are added.

The curvature of protofilaments at the ends of depolymerizing microtubules, and the fact that the products of depolymerization are often curved oligomers, suggests a structural basis for the coupling of nucleotide hydrolysis and polymerization. Before hydrolysis, the GTP-containing dimers are probably straight, fitting snugly into the growing microtubule lattice. If the GDP-containing subunits are naturally curved, then they would be strained when trapped within the lattice. In this way, energy from hydrolysis could be stored within the lattice as mechanical strain.

3.9 Motility Assays with Cytoskeletal Filaments

Several *in vitro* experiments show that polymerization of pure actin or tubulin, without any additional proteins, can generate pushing force and do mechanical work. Polymerizing actin filaments inside

liposomes causes distension of the liposomes, demonstrating that the growing filaments can push outward on the lipid bilayer. Likewise, microtubule filaments grown inside a small chamber can push against the chamber walls with enough force to buckle themselves (Fig. 1e). By analyzing the shapes of buckled filaments, the maximum pushing force of a single microtubule has been estimated at 4 pN.

These important experiments prove that growing filaments can push against an object, but they are incomplete models for the polymer-driven motility that occurs in cells. In cells, a variety of accessory proteins provide spatial and temporal control of filament dynamics, and couple the ends of growing and shrinking filaments to other structures to apply force. *Listeria* promote spatially localized actin polymerization with a nucleation factor, ActA. Likewise, kinetochores contain a host of proteins that modulate microtubule dynamics and maintain attachment to microtubule ends. Understanding the mechanisms of these accessory factors will be key to understanding how cells harness cytoskeletal filaments to produce motion and force.

In vitro motility assays that reconstitute force generation using dynamic filaments coupled to accessory proteins provide more realistic models for filament-based motility in cells. Shrinking microtubules can pull against microscopic beads when the beads are coated with proteins that maintain attachment to the depolymerizing filament ends. This motion is similar to the way chromosomes are pulled apart before cell division, and also to the way the mitotic spindle is positioned inside asymmetrically dividing yeast cells. In a reconstituted assay that closely mimics the motion of *Listeria*, beads coated with ActA protein are pushed around by actin polymerization. The beads follow curved trajectories and leave comet tails of polymerized actin in their wake, just like the bacteria.

4 Conclusion

Motion is fundamental to life. Everyone is familiar with the macroscopic motion of muscle contraction. There are also exquisite motions taking place at the level of cells and molecules. The cells in our immune system crawl around our bodies and engulf invading bacteria. Cilia in our lungs beat to remove inhaled debris. In all these cases, the motion is generated by tiny protein machines, the molecular motors. Molecular motors are ubiquitous, and the list of known motors is growing. Besides the classic motors, myosin, kinesin, and dynein, and the cytoskeletal polymers, filamentous actin and microtubules, there are also protein machines at the heart of energy metabolism, and reading the genetic code. Studies of molecular motors, particularly *in vitro* work with single molecules, have revealed fascinating details about how they convert chemical energy into mechanical work.

While motors are arguably the most machinelike of the biological molecules, they are certainly not the only things inside living cells that remind us of man-made apparatus. The action at a distance that occurs within an allosteric enzyme, for example, is reminiscent of the push rods or levers inside an internal combustion engine. The large, multienzyme complexes that cells use to carry out sequences of reactions remind us of assembly lines. However, molecular

motors are an important special case because the motions they produce are large enough to be directly measured. The study of motor proteins offers rare, direct access to address general questions about how a protein's structure dictates it's dynamics and function.

Keywords

Adjuvant
(Latin: *adjuvere* to help) substances added to vaccines to increase immune responses.

Antigen
Foreign substance recognized by immune system.

B Cells
Lymphocytes that make immunoglobulin (antibody); can also present antigens.

T Cells
Lymphocytes that require the thymus for development.

Th1 Cells
Typically make interferon (IFN)-gamma and tumor necrosis factor (TNF) and activate macrophages to kill intracellular pathogens and switch on IgG1 production from B cells.

Th2 Cells
Make cytokines such as IL-4, IL-5, and IL-13, which promote growth, activity, and survival of eosinophils and switch B cells to make IgE.

Chemokines
Chemoattractive proteins made by many cell types that cause cell recruitment to inflamed tissues.

Cytokines
Small proteins produced by T cells that act as signals to other cells of the immune system or structural cells (e.g. IL-1, IL-3, IL-4, IL-5, IL-10, and IFN).

Lymphocytes
White blood cells that concentrate in lymph nodes, spleen, and so on.

Vaccine
A substance administered to trigger memory immune responses that protect against disease.

The immune system faces a dilemma. It must tolerate benign commensal organisms and antigens present in food and air, while rapidly mounting vigorous responses to the plethora of pathogens that enter via mucosal surfaces. The existing mucosal vaccines against poliomyelitis, influenza, and measles were developed on a largely empirical basis against transient self-limiting infections that themselves induce lifelong immunity.

In this article, we review the successes and failures of mucosal immunization and the opportunities for exploiting developments in immunology to create new and effective mucosal vaccines. The challenge now is to exploit new information about immunoregulation to develop effective vaccines against more subtle agents that circumvent lifelong immunity, recur, or persist.

1 Introduction

The mucous membranes lining the lung, gut, and urogenital tract present unique problems to the host defense systems. They have specialized functions that necessitate close contact with the environment, yet most common infections enter by these routes. Immune defenses at mucosal surfaces therefore have to defend against pathogens while being tolerant of nonthreatening substances in food and inhaled air. Both innate and acquired mechanisms of immunity are involved in preventing microbial entrance and spread. Mechanisms of acquired immunity combine humoral (production of antigen-specific secretory IgA, S-IgA) and cell-mediated immune responses (Fig. 1).

Mucosal immunization has the potential to induce protective immunity against infectious diseases or to elicit antigen-specific tolerance. The mucosal immune system has to be appropriately activated to achieve effective protection against colonization and invasion by infectious agents at mucosal surfaces. Although administration of vaccines directly to mucosal sites has many advantages, mucosal immunity can be also achieved by other routes of antigen delivery. However, in this review we focus primarily on the mucosal route of vaccination.

Because of the low absorption efficiency of mucosally delivered vaccines, almost all current vaccines are administered parenterally. In addition, suboptimal immune responses are frequently induced by mucosal immunization and the use of mucosal adjuvants is required. As a result, development of successful mucosal vaccines depends largely on improvements to mucosal delivery systems and on the discovery of new and effective mucosal adjuvants (Fig 2).

2 Goals of Mucosal Vaccination

Most environmental pathogens enter the body through the mucosal membranes of the intestinal, respiratory, or genital tract. Some only replicate in the mucosa, but others use the mucosa to gain entry before dissemination to other sites. For purely mucosal infections (e.g. those caused by most common cold agents and infective diarrheal organisms), prevention of initial

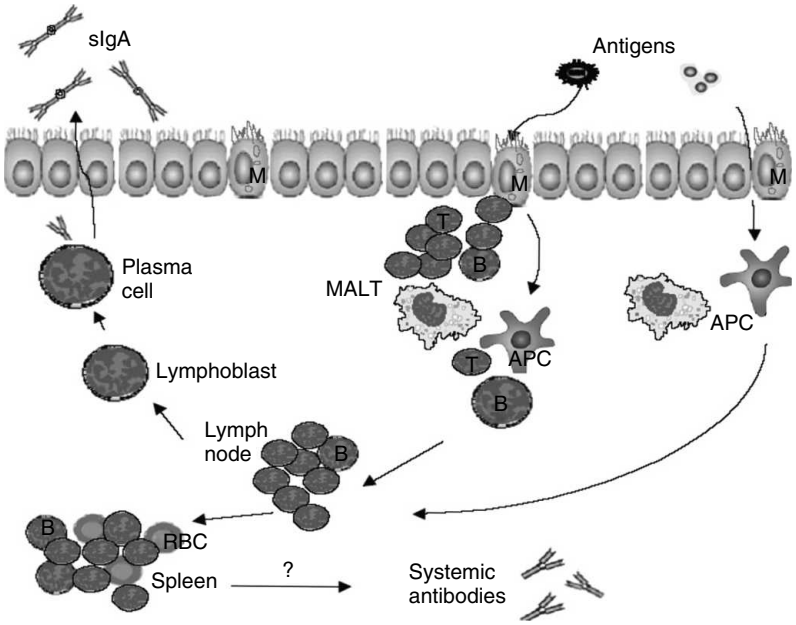

Fig. 1 Schematic representation of cells involved in immune reactions after mucosal challenge. APC, antigen-presenting cell; M, microfold epithelial cell; T, T cell; B, B cell; RBC, red blood cell.

colonization is an essential but difficult aim of vaccination; when dissemination or toxin production is essential to disease pathogenesis, prevention of surface invasion may not be necessary.

Mucosal vaccination is an attractive administration route for mass vaccination, as it does not require trained medical personnel and does not involve needles and syringes These factors affect the costs of vaccination and the risk of transmitting blood-borne infections (HIV or HepB) making mucosal vaccine particularly attractive for use in developing countries (Table 1).

New or improved vaccines are needed for a wide range of mucosal infections, including respiratory tract infections caused by *Mycobacterium* spp, *Mycoplasma pneumoniae*, influenza virus, rhinovirus, coronavirus, adenovirus, human metapneumovirus, and respiratory syncytial virus (RSV); urogenital tract infections caused by *Chlamydia*, HIV, *Neisseria gonorrhoeae*, *Treponema pallidum*, and herpes simplex virus (HSV); and gastrointestinal infections caused by *Escherichia coli*, *Salmonella*, *Shigella* spp, *Helicobacter pylori*, *Vibrio cholerae*, *Campylobacter jejuni*, *Clostridium difficile*, and rotaviruses. The challenge is to design vaccine preparations that induce neutralizing immunity to the pathogen or their toxins, preventing their attachment to mucosal surfaces, tissue invasion, and spread (Fig 3).

Induction of specific secretory IgA (S-IgA) is an essential aim of mucosal vaccination. Locally produced S-IgA is considered to be among the most important protective humoral immune factors and constitutes over 80% of all antibodies produced in mucosa. In humans, S-IgA

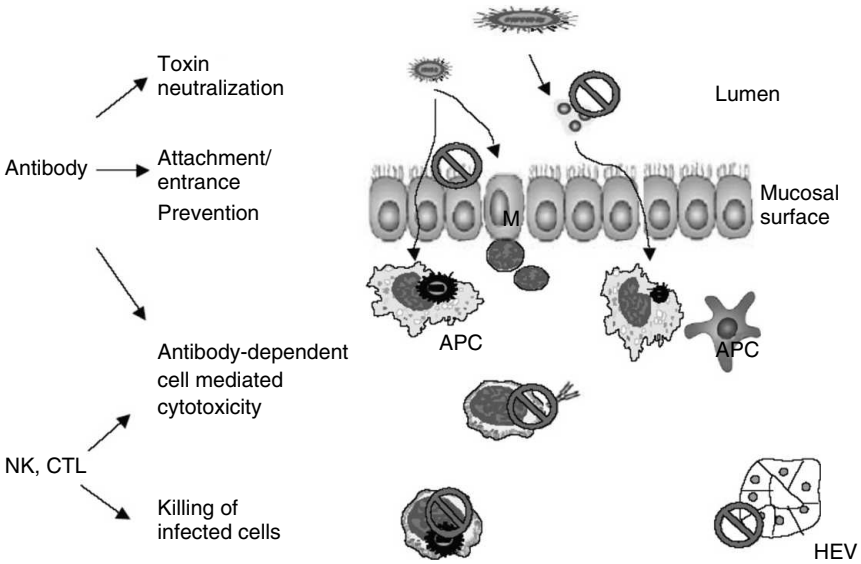

Fig. 2 Goals of mucosal immunization. Successful mucosal immunization may induce humoral and cellular immune responses. Possible roles of both are shown. M, microfold epithelial cell; HEV, high endothelial venule; APC, antigen-presenting cell; the Ø symbol indicates possible sites of immune intervention.

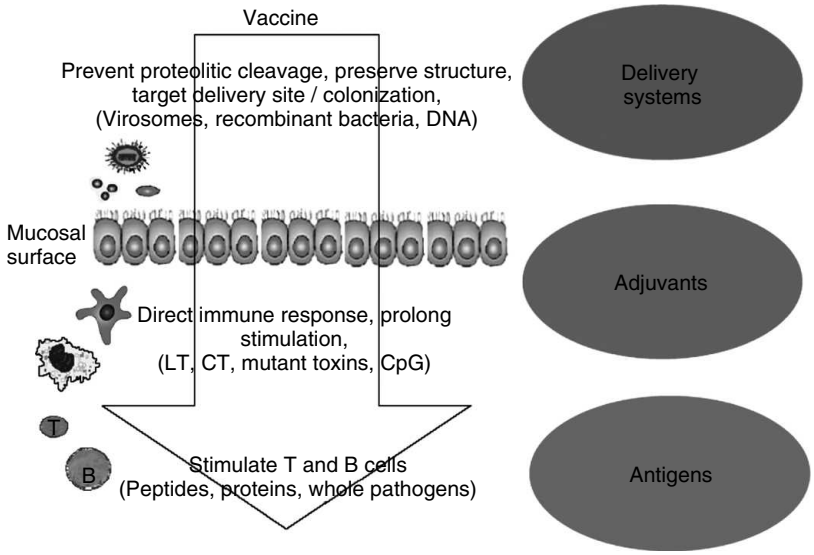

Fig. 3 Challenges for mucosal vaccination: schematic representation of key issues in mucosal vaccine development.

Tab. 1 Comparison of mucosal and parenteral delivery of vaccines.

Vaccination	*Mucosal*	*Parenteral*
Administration	Easy, self administration	Need of trained personnel
Risks	Nonaccurate dosing	Infection (HIV, Hepatitis B)
Antigen dose	Usually high	Low
Formulation	Need of mucosal adjuvant	Mixed with Alum
Immune responses	Stimulates mucosal immunity but may induce tolerance	Rarely induces mucosal responses but good systemic antibody and T cell responses
Use in human	Only few vaccines	Most of the vaccines

antibodies are usually dimeric whereas serum IgA is mainly monomeric. Antibodies secreted by mature plasma cells in various compartments of the common mucosal immune system are able to interact with invading pathogens, inhibit their attachment, and form immune complexes with potentially harmful molecules (immune exclusion). S-IgA may neutralize viruses and directly participate in antibody-dependent cell-mediated cytotoxicity (ADCC) in collaboration with macrophages and lymphocytes. However, natural killer cells and specific cytotoxic T cells are also key defenses in preventing infection with intracellular pathogens (Fig. 2). In testing vaccine efficacy, both antibody levels and cellular immunity should therefore be monitored.

3
Benefits of Mucosal Vaccination

3.1
Main Features of the Common Mucosal Immune System

A key issue in mucosal immunity is the necessity to distinguish between normal antigens, which are not harmful, and those that belong to dangerous pathogens. The discrimination between hazardous and nonhazardous antigens is determined by activation by pattern-recognition receptors (including Toll-like receptors), which may be displayed in intestinal crypts or in the cytoplasm of mucosal cells, and are therefore inaccessible to nonhazardous commensals. The anatomical placement of pattern-recognition receptors in inaccessible sites appears to be an important factor in allowing discrimination between hazardous and nonhazardous antigens.

The mucosal immune system is highly adapted toward tolerance, the breakdown of which can result in disease (e.g. celiac disease). Mucosal exposure frequently induces regulatory T cells, of which there are several distinct types. First, Th3 cells produce transforming growth factor beta (TGF-beta); these are frequently induced by repeated feeding of low doses of antigen orally. Second, Tr1 cells are a subset of CD4 T cells, which produce IL-10, the production of which is promoted by IL-15 and Type 1 interferon. Third, CD4+ CD25+ cells are potent regulators of autoreactivity *in vivo* and can also be induced by tolerogenic oral feeding. Fourth, CD8 T cells often have a regulatory role in the gut, but their exact functions have not been clearly defined. In addition,

there is mounting evidence that gamma delta T cells may, under some conditions, also promote a tolerogenic state after oral feeding. All these subsets are readily induced by oral administration of antigen, but induction must be avoided if mucosal vaccination is to be successful.

3.2 Distinctive Characteristics of Mucosal Immunity

In mammals, immune responses at mucosal surfaces are provided by a defence system known as *mucosa-associated lymphoid tissue* (MALT). It comprises an integrated network of cells and molecules anatomically grouped and functionally divided into sites of antigen uptake and effector function. Mucosal immune responses are triggered in specialized zones that sample foreign material from the epithelial surface. The main inductive site of the upper respiratory tract is in the nasal-associated lymphoid tissue (NALT), and in the gastrointestinal tract it is the Peyer's patch (PP), the appendix, and the solitary lymphoid nodules, collectively called the *gut-associated lymphoid tissue* (GALT).

The respiratory epithelium contains four different cell types: alveolar macrophages, dendritic cells, M cells, and intraepithelial lymphocytes. The latter are relatively scarce in the respiratory tract. M cells are associated with lymphoid structures and differ in morphology from absorptive cells by their short microvilli, small cytoplasmic vesicles, and few lysosomes. The M cells selectively absorb antigen by endocytosis or pinocytosis and direct it to professional APC (macrophages, dendritic cells, B lymphocytes) or directly process and present antigen to T cells (Fig. 1). In the gut, specialized M cells are thought to provide the main route by which complex antigens gain access to the immune system. Lymphocytes primed in the Peyer's patches express $\alpha_4\beta_7$ integrin, which binds to the mucosal adressin cell-adhesion molecule 1 (MAD-CAM1), which is expressed at high levels by the vascular endothelium in mucosal surfaces. Gut-derived T cells also express the chemokine receptor CCR9, which allows them to respond to the chemokine CCL25, which is expressed selectively by small bowel epithelial cells. By contrast, T cells that are primed peripherally typically display the $\alpha_4\beta_1$ integrin and CCR4 and so do not migrate or respond in mucosal sites. This selective expression explains why mucosal vaccination is often required to protect against mucosal infections, and why peripheral administration of vaccine antigens is often ineffective against mucosal infections. The establishment and maintenance of the immune response requires close cooperation between many cell types. Activated T cells help B cells to develop into plasma cells, a process that depends on the nature of the antigen and on the cytokines produced by T helper cells. TGF-β, IL-10, and IL-4 promote the switch from IgM to IgA production from stimulated B cells. Precursors of mucosal plasma cells derive from lymphoepithelial structures, mature in the regional lymph nodes, and enter the circulation via the thoracic duct. Then they can seed the lamina propria of distant mucosal sites (e.g. intestines, respiratory tract, genital tract, salivary gland, etc.), where they differentiate. In this way, antibodies can appear at different mucosal sites elsewhere within the common mucosal immune system. Natural killer cells may be also present in mucosal tissues and, together with

CTLs, are important for eliminating virus-infected cells.

There is strong evidence that various mucosal sites of the immune system can communicate. For instance, within 24 h of adoptive lymphocyte transfer, mesenteric lymph node (MLN) cells are found in recipient gut, cervix and vagina, uterus, and mammary glands. The ability of cells to migrate between mucosal zones has been extensively investigated. Thus, intranasal immunization may induce specific immunity in intestine, and boosted levels of IgA have been reported in the intestine after intranasal (rather than oral) administration. In these experiments, the relatively poor induction of gut immunity by oral administration could be due to degradation of antigen and dilution in the contents of the gastrointestinal tract.

Several examples show that intranasal immunization can result in efficient immunity at distant mucosal sites. For instance, intranasal administration of a recombinant HIV envelope protein formulated in CTB-associated GM1 lipid vesicles enhances mucosal IgA antibody responses in nasal and gut tissues. Administration of a DNA vaccine for herpes simplex induces antigen-specific cellular and secretory IgA responses in the gut, vagina, and oral cavity after intradermal, intraperitoneal, intravaginal, intranasal, or oral immunization. Taking advantage of the functional integrity of the common mucosal system, vaccines easily administrated into the nose may in the future include those against herpes simplex virus or HIV. For instance, recombinant adenovirus used to deliver antigens derived from HSV and HIV has been demonstrated to induce protective immunity in mice vaginal mucosa, particularly when cholera toxin was included in the vaccine preparation.

3.3 Multivalent Mucosal Vaccines

Delivery systems that allow simultaneous delivery of several antigens derived from one or more pathogens may be used to design a multivalent vaccine. Such a vaccine potentially may reduce the number of administrations needed and increase protection in the populations studied.

For example, RSV and human parainfluenza represent two of the most important viral agents of pediatric respiratory tract disease worldwide. Studies are under way that use recombinant bovine/human parainfluenza virus type 3 (rB/HPIV3), with bovine F and HN genes replaced with their HPIV3 counterparts and expressing the major surface antigens of respiratory syncytial virus. Both recombinant viruses were shown to replicate efficiently in the respiratory tract of hamsters and induced serum antibody titers similar to those induced by RSV or HPIV3 infection. Immunization of hamsters with rB/HPIV3-G1, rB/HPIV3-F1, or a combination of both viruses resulted in high level of resistance to challenge with RSV or HPIV3 28 days later. Schmidt et al. described a similar strategy for intranasal immunization against RSV subgroups A and B and human parainfluenza virus type 3 by using a live cDNA-derived vaccine in monkeys.

3.4 Edible Vaccines

Transgenic plant technology allows the production of large quantities of transgenic antigen from pathogenic microorganisms at low cost and would have particular benefits in underresourced areas. The first edible vaccine was obtained by inserting the gene encoding hepatitis B surface

antigen into tobacco plants, resulting in an antigen very similar to that obtained from recombinant yeast. Similar methods have been used to make vaccines containing genes of *E. coli* heat-labile enterotoxin B (LT-B), rabies virus glycoprotein, F protein of RSV, Norwalk virus capsid protein, and *V. cholerae* (CT-B) in potatoes, tomatoes, and other plants. Materials from recombinant plants have been shown to be immunogenic in feeding experiments in animals, inducing systemic and mucosal responses, and promising clinical trials show that specific anti-LT-B responses can be demonstrated in humans given transgenic potatoes expressing LT-B. The possibility of using transgenic plants for the production of specific immunoglobulins for passive immunotherapy is also being explored, but the commercial viability of these technologies is unproven.

Oral administration could theoretically induce tolerance to pathogens, resulting in serious adverse consequences. Fear of this effect has limited the clinical trials of oral vaccination against hepatitis B with edible potatoes expressing hepatitis surface antigens to preimmune individuals.

3.5 Overcoming Preexisting Immunity or Tolerance

Immunity to vaccinia potentially limits the utility of vaccinia vectors in people previously immunized against smallpox. However, the studies of Belyakov et al. suggest that modified vaccinia Ankara (MVA) expressing HIV gp160 could successfully immunize via the mucosal route and induce potent specific systemic humoral and CTL responses in vaccinia-immune mice. It therefore seems possible that immune responses at mucosal sites may not be prevented by prior systemic immunization and that this mucosal naiveté may be exploited in generating immune responses in previously vaccinated individuals.

Another challenge to immunization against RSV and measles is the inefficiency of vaccination in the presence of specific maternal antibody. It appears that mucosal immunization may overcome this difficulty. Mutwiri et al. concluded from studying immune responses in neonatal lambs that enteric immunization with a human adenovirus vector may be an effective approach for inducing both mucosal and systemic immune responses in neonates. Similarly, in the cotton rat model of measles mucosal vaccination with vesicular stomatitis virus expressing the hemagglutinin of measles virus induces seroconversion in the presence of maternal antibodies and leads to protection against measles challenge. On the basis of experience with highly effective live polio vaccine given at birth, it has been proposed that mucosal immunization may be safer and more effective than any other route of vaccination in young children.

4 Challenges for Mucosal Immunization

4.1 Mucosal Delivery Systems

4.1.1 Live Bacterial Vectors

Commensal flora as expression vectors
Genetic manipulation of normal surface bacteria is attractive in that no pathogen is deployed in vaccine production and the bacteria themselves can exhibit probiotic properties. However, the risk is that such bacteria will be tolerated and thus no immune response will be generated. Considerable work has been done

with *Lactococcus lactis*, some strains of *Lactobaccillus*, *Staphylococcus carnosus*, and *Streptococcus gordonii*. These bacteria are noninvasive or commensal organisms in healthy people. Internal adjuvanticity is provided by peptidoglycan, and lactobacilli tagged with green fluorescent protein are actively taken up by APC after intranasal administration, suggesting that antigens would be processed and presented. Recombinant antigens that have been expressed in commensal bacteria include the V3 domain of HIV-1 gp120, fusion and hemagglutinin from measles virus, fragment B of diphtheria toxin, peptides from *Plasmodium falciparum,* and epitopes from RSV.

Pathogens as expression vectors Many bacterial pathogens naturally invade via mucosal surfaces and induce strong mucosal immunity. Attenuated *Salmonella* has been extensively studied as a vector both for oral and intranasal delivery. Interestingly, i.n. vaccination induces better systemic and local immune responses to inserted antigens (e.g. hepatitis B core antigen) than oral or rectal immunization. Insertion of antigens from *Helicobacter pylori* into *Salmonella*, for instance, results in induction of specific CD4+ T cells producing IFN (interferon) and IL-10 in a mouse model, as well as good protection after just two i.n. doses of vaccine.

Attenuated strains of *Shigella* are also promising live bacterial vectors. In animal models, they were shown to induce specific serum antibody responses (IgG and IgA) to inserted antigens after i.n. immunization.

Bacille Calmette-Guérin (BCG) is the first attenuated vaccine introduced to humans and still is the most widely used vaccine in the world, since it is the only one available against tuberculosis. Since BCG induces cellular immunity and can accommodate foreign epitopes, it may work as a successful vector when specific cellular responses are needed. The safety of the vaccine given at birth suggests its relevance for immunizations is required very early in life. Candidates would therefore include measles and RSV vaccine. Indeed, recombinant BCG producing measles nucleoprotein provided protection against virus challenge in intranasally immunized infant rhesus macaques. Other examples of heterologous antigens expressed in BCG for mucosal vaccination include HIV, human papilloma virus, *Schistosoma haematobium*, *Plasmodium yoelii*, and *Toxoplasma gondi*.

Recently, attenuated *Bordetella pertussis* emerged as a bacterial vector for i.n. vaccination. Deletion of genes coding for pertussis toxin diminished the virulence of the bacteria but preserved their ability to colonize mucosal sites. Interestingly, the immunogenicity to the mayor antigen, filamentous hemagglutinin (FHA) was increased, as well as that to heterologous antigen fused to FHA. Additionally, significant protection was observed in a mouse model of *Schistosoma mansoni* infection following single i.n. immunization.

4.1.2 Virosomes

Cusi et al. investigated the efficacy of a vaccine composed of the RSV fusion protein associated with influenza virosomes (IRIV), which was administered intranasally together with *E. coli* heat-labile toxin (LT). After an intramuscular ''priming'' with influenza virus vaccine, mice were i.n. immunized with RSV-F/IRIV + LT or with RSV-F + LT or IRIV + LT. The results showed that mice immunized with RSV-F + LT developed Th2 type responses and that virosomal delivery greatly potentiated immune responses in animals. All mice immunized with RSV-F/IRIV + LT developed a balanced Th1/Th2 cytokine

profile with mucosal IgA and high levels of serum IgG. More importantly, histological analysis of lung tissue of RSV-challenged mice did not reveal vaccine-enhanced pulmonary eosinophilia.

4.1.3 Mucosal DNA Vaccines

The immunogenic potential of DNA vaccination has been extensively tested in animal models. DNA vaccination has many theoretical advantages, including ease of production, stability of vaccine preparations, and the ability to induce both antibody and cell-mediated immune responses. The drawbacks are that success in animal models is poorly predictive of outcome in human studies and that long-term follow-up studies are necessary to assess the risk of vaccine involvement in autoimmune diseases or immune disregulation.

DNA is not usually taken up in non-degraded form from mucosal surfaces. However, DNA immunization in mice and chickens has been shown to induce antibodies to influenza nucleoprotein and to trigger both mucosal and systemic cellular protective immune responses. In a recent study, Sasaki et al. described immune responses induced by intranasally and intramuscularly delivered DNA encoding HIV-1 proteins in mice. Both routes produced similar levels of cell-mediated immunity, but intranasal immunization induced higher levels of intestinal S-IgA than intramuscular immunization, and the adjuvant QS21 enhanced both intranasal and intramuscular immune responses.

Encapsulation of DNA into microparticles prevents degradation of DNA and enhances immunogenicity; therefore, it is an attractive delivery system for a mucosal DNA vaccine. Such a vaccine, designed using rotavirus VP6 DNA encapsulated in PLG microparticles, was shown to be effective in inducing systemic and mucosal immunity after oral administration to mice.

4.2 Mucosal Adjuvants

Many substances are known to have adjuvant properties; however, the majority are used for parenteral immunization and only a few are suitable for the mucosal route. Alum, the only universally licensed adjuvant for use in humans, is not a suitable adjuvant for mucosal immunization. The choice of an appropriate adjuvant for mucosal vaccination is very important to its success. Many mucosal adjuvants are based on bacterial toxins and their derivatives, CpG-containing DNA, and various cytokines and chemokines. Since most antigens are poorly immunogenic when introduced via the mucosal route if no adjuvant is added, induction of tolerance is likely.

4.2.1 Biodegradable Polymeric Particles

Micro- and nanoparticles may be used to encapsulate vaccine antigens. Many such polymers have the advantages of being biodegradable and at the same time of protecting the antigen from premature degradation. Slow degradation of polymers controls the release of entrapped antigen; therefore, such vaccines can induce immune responses over prolonged periods of time. Poly(D,L-lactide-co-glycolide) (PLG) polymer is probably the most extensively studied polymer because of its safety record in humans. The hydrolysis of PLG polymer to release encapsulated antigen is controlled by the polymer composition and its molecular weight. PLG particles may be suitable mucosal vaccine carriers, as shown by using fimbriae from

B. pertussis encapsulated in PLG particles for oral delivery to mice. The technique was able to induce serum and mucosal antibody responses in mice as well as to protect against live bacterial challenges. Baras et al. demonstrated recently the feasibility of long-term *in vivo* release of antigens from PLG particles. They showed that a single nasal or oral immunization of glutathione S-transferase from *S. mansoni* in PLG microparticles could induce a long-lasting antigen-specific antibody response in mice, with a peak at 9 to 10 weeks after immunization.

4.2.2 **Bacterial Toxins**

Bacterial toxins have been used for a long time as adjuvants in experimental models, and some chemically detoxified toxins have been employed to prevent bacterial infectious diseases (e.g. formalin inactivation of *Corynebacterium diphtheriae* or *Clostridium tetani* exotoxins). Although bacterial toxins possess excellent adjuvant properties, they have been prohibited from wide use as adjuvants in humans because of their high toxicity. Two bacterial toxins have found particular attention for application as mucosal adjuvants: cholera toxin (CT) produced by *V. cholerae* and heat-labile enterotoxin (LT) produced by *E. coli* have similar structures, since both contain subunits A and B and the toxicity originates from the A subunit, which catalyzes ADP-ribosylation of the stimulatory GTP-binding proteins on the surface of the epithelial cells and raises the intracellular levels of cAMP. This then leads to secretion of water and electrolytes into the mucosal lumen. Today it is possible to obtain detoxified derivatives by mutagenesis of the toxin genes. With this technology, the genes are modified in such a way as to encode different amino acid(s) that are no longer able to function in enzymatic activity. Such inactivated substances are safe and in the future could replace toxoids in existing vaccines as well as be used as mucosal adjuvants in new vaccination strategies.

Several mutant toxins have already been described; among them are mutations of the heat-labile toxin of *E. coli*: LTK63, LTR72, and LTG192. All of them have been studied in detail for their ability to induce systemic and local immune responses to coadministered antigen. LTR72 was the strongest adjuvant, as compared with the fully nontoxic LTK63 mutant, and showed only 0.6% of the enzymatic activity of the wild-type LT. LTK63 was shown to be 100 000-fold less toxic but 20 times less effective than LT. Moreover, CD4+ lymphocytes from animals immunized with ovalbumin together with LTR72 exhibited very strong proliferative responses, similar to those induced by wild type LT. LTK63 was also tested in the murine measles model, and mucosal coimmunization with the mutant and a synthetic peptide representing a CTL epitope from measles N protein was very effective in *in vivo* priming of peptide-specific and measles virus–specific CTL responses. Similarly, the addition of LTK63 to peptide RSV vaccine induced strong CTL responses and protection after intranasal administration into a mouse. Compared with administration of oral influenza vaccine alone, coadministration of vaccine with LTG192 provided enhanced protection from infection in the upper and lower respiratory tract, equivalent to and at similar doses as that obtained with wild-type LT. The mutant toxin augmented virus-specific IgG and IgA responses in serum, lung, and nasal washes and also the numbers of virus-specific antibody-forming cells in spleen, lung, and Peyer's patches in a manner comparable to that of wild-type LT.

Studies conducted in experimental animals have given promising results with respect to immune responses developed after intranasal vaccination by a number of delivery systems. Cholera toxin B given intranasally with measles virus stimulated systemic neutralizing antibodies, and intranasal immunization with a chimeric synthetic peptide containing two T-helper epitopes (MVF: aa 288–302) and one B-cell epitope (MVF: aa 404–414) produced both systemic and mucosal antibody responses that conferred protection against encephalitis after infection with neuroadapted measles virus.

A novel nontoxic form of chimeric mucosal adjuvant that combines the A subunit of mutant cholera toxin E112K with the pentameric B subunit of heat-labile enterotoxin from enterotoxigenic *E. coli* was constructed. Nasal immunization of mice with tetanus toxoid (TT) plus the new adjuvant elicited significant TT-specific immunoglobulin A responses in mucosal compartments and induced high serum immunoglobulin G and immunoglobulin A anti-TT antibody responses.

The suitability of CT and LT and their mutants in human vaccinology remains to be determined. Several clinical trials did not report side effects; however, at least one influenza vaccine coadministered with LT had to be withdrawn from study due to several instances of facial paresis.

4.2.3 CpG Oligodinucleotides

Synthetic oligodeoxynucleotides (ODN) that contain unmethylated CpG motifs (CpG ODN) are also novel candidates as adjuvants for mucosal immunization. Initially, it was reported that these motifs could induce *in vitro* production of IL-6 and IFNγ by CD4+ T cells, IL-6 and IL-12 by B cells, and IFNγ by NK cells. Such properties led to the use of CpG ODNs as an adjuvant in several experimental models and indeed, work published so far supports the view that Th1-type responses dominate after CpG coadministration with an immunogen. However, some authors indicate that these responses are very much dependent on the age of the primed animals, the route of antigen delivery, or the nature of the antigen. The potential of CpG motifs as adjuvants for delivery via mucosal surfaces is particularly promising, as can be judged from several recent publications.

4.2.4 Cytokines and Chemokines

Cytokines can be used as mucosal adjuvants, either added directly to a vaccine preparation or encoded in DNA. Recent advancements in cytokine applications are summarized in Table 2. As an example, combination of IL-1 and IL-12 or IL-18 and GM-CSF creates a potent stimulating environment for mixed Th1/Th2 immune responses with the effect of IFNγ, IgA, and induction of CTL responses. IL-2 and IL-6, coexpressed in recombinant bacteria, significantly increase specific antibody in serum as well as in mucosal IgA subsequent to i.n. inoculation in mice. Likewise, some chemokines are being explored for use to potentiate mucosal immunity, as reported by Lillard et al. and Eo et al. Particularly promising is RANTES, which is a chemoattractant for monocytes, T cells, and NK cells, and has strong ability to induce Th1 responses, particularly CTLs. Moreover, nasal coadministration of RANTES with a protein antigen was demonstrated to augment Th1 and Th2 local and systemic immune responses.

4.2.5 Saponins

Saponins purified from the bark of the tree *Quillaja saponaria molina* and their

Tab. 2 Examples of cytokines and chemokines coadministered with mucosal vaccines.

Cytokine/ chemokine	*Delivery system*	*Model*	*Route of delivery*	*Effect*
GM-CSF	Adenovector	Mouse	Intranasal	Increased IgG2a and IgG1, elevated levels of IFN-γ, TNF-α, and IL-10
	Plasmid DNA	Mouse	Rectal/ vaginal	Increased serum IgG, enhanced mucosal and fecal IgA
IL-2	Plasmid DNA-encapsulated in PLG microparticles	Mouse	Oral	Enhanced CTL responses
	Recombinant *L. lacti*	Mouse	Intranasal	Increased antibody titers
	Liposomes *s*	Mouse	Intranasal	Increased *P. aeruginosa* polysaccharide-specific pulmonary plasma cells, reduced mortality from pneumonia
IL-4	Plasmid DNA	Mouse	Rectal/ vaginal	Increased antibody levels; decreased CTL activity
IL-6	Recombinant *L. lactis*	Mouse	Intranasal	Increased antibody titers
IL-12	Liposomes	Mouse	Oral	Shift to IgG2a and IgG3, decreased IgE Abs, enhanced serum IFN-γ
	Plasmid DNA	Mouse	Rectal/ vaginal	Decreased antibody levels, enhanced CTL activity
IL-1alpha, IL-12, and IL-18	Peptide	Mouse	Intranasal	Specific anti-HIV IgA in saliva, fecal extracts, and vagina
RANTES	Peptide	Mouse	Intranasal	Augmented Th1 and Th2 responses
IL-10	Plasmid DNA	Mouse	Intranasal	Diminished Ag-induced delayed type hypersensitivity, production of Th1 cytokines
CCR7 ligands	Plasmid DNA	Mouse	Intranasal, intragastric	CD4+ T helper cell proliferation and CD8+ T cell-mediated CTL activity, serum IgG

derivatives are being used experimentally for mucosal immunization. Quil A can be incorporated into more potent adjuvant systems, such as ISCOMs (see below). Onjisaponins were shown in studies of Nagai et al. to be safe and potent adjuvants for intranasal inoculation together with influenza and DTP vaccines. Experiments in mice showed that the use of adjuvant significantly increased serum IgG and nasal IgA as well as inhibited proliferation of mouse-adapted influenza virus in BAL of infected mice.

4.2.6 Immune Stimulating Complexes (ISCOMS)

ISCOMs (immune stimulating complexes) consist of cholesterol, phospholipids, viral proteins, and glycosides of the adjuvant Quil A. For several viruses, it has been shown that the incorporation of viral proteins into the ISCOM structure can

dramatically enhance their immunogenicity. Strong B-cell and T-cell responses are usually observed together with induction of CTL responses, which are normally not evoked by nonreplicating vaccine preparations. ISCOM-based influenza vaccines are currently being evaluated in clinical trials, and initial studies have shown that individuals immunized with ISCOM preparations developed virus-specific CTL responses in addition to strong antibody responses.

Intranasal delivery of inactivated influenza vaccine plus the ISCOMATRIX^{Ø} (IMX) adjuvant was able to induce serum hemagglutination inhibition (HAI) titers in mice better than those obtained with nonadjuvanted vaccine delivered subcutaneously. Furthermore, the IMX-adjuvanted vaccine delivered intranasally induced mucosal IgA responses in the lung, nasal passages, and large intestine, together with high levels of serum IgA.

4.2.7 MF59

MF59 is an adjuvant approved for use in humans and elicits higher antibody titers than alum when used in combination with a variety of recombinant and natural subunit antigens. MF59 is an oil-in-water emulsion that contains squalene (a metabolite of cholesterol), polysorbate 80 (a surfactant soluble in water), and sorbitan trioleate (a surfactant soluble in oil). Although the mechanisms responsible for the adjuvant action of MF59 are not fully understood, enhancement of humoral immune response to parenteral influenza vaccine has been shown in humans, and mucosal immune responses to intranasally administered influenza vaccine were evoked in mice. Thus, it appears that MF59 may be a promising formulation for future mucosal vaccines.

5 Vaccination via the Respiratory Tract

The first point of contact for inhaled pathogens is usually the nasal mucosa. Many infections are initiated at the mucosal surface and so it would appear desirable to induce neutralizing antibodies and specific cellular responses at the site of pathogen entry. The large, highly vascularized surface (150 cm^2) has the potential of very efficient absorption of delivered vaccine, and the presence of immune cells in this area enables the initiation of immune reactions. Nasal epithelium absorbs principally soluble antigens, so use of a suitable delivery system is likely to contribute to achieving protective responses after immunization via the nasal route.

The technique of intranasal immunization is very important if large doses are administered. Some vaccine may be swallowed, leading to oral delivery, or, in anesthetized animals, a proportion of the vaccine may reach the lung. The epithelial deposition of antigens in the respiratory mucosa depends on size of particles (aerodynamic diameter); therefore, in designing a vaccine for delivery via the respiratory route particle size is a critical issue.

5.1 Applications of Nasal Vaccination

Many preclinical studies have been conducted on vaccines administered via the respiratory tract. These are mostly delivered into nasal mucosa, but some trials involving deep lung deposition have also been described. As mentioned above, the functional integrity of mucosal system allows induction of immune responses in sites distant from the immunization site. It seems obvious, however, that intranasal

immunization is particularly appropriate for prevention of those infectious diseases acquired by inhalation. Therefore, we focus here on recent developments of nasal vaccines against some respiratory viral diseases.

The protective efficacy of mucosal immunization with purified RSV fusion protein (F) or chimeric FG glycoprotein was shown in animal models when the vaccines were coadministered with CT adjuvant. Complete protection was also demonstrated in mice immunized with a synthetic peptide (residues 174–187) of the G protein mixed with CT, even though the peptide failed to induce a detectable level of secretory IgA. Effective mucosal immunization against RSV was reported after using F protein and a genetically detoxified toxin CT-E29H or CTL peptide from the M2 protein together with LTK63 as an adjuvant.

Recently, live, attenuated, cold-adapted viral vaccines have been developed as alternatives to inactivated vaccines. Thus, it is possible to produce an organism that replicates efficiently at 25 to 28 °C, that is, the temperature of the nasal passage, but not at 37 °C (the temperature of the lungs). Intranasal administration of cold-adapted vaccines usually induces good immune responses – including local IgA responses and secretory IgA antibodies, which can provide protection against pathogens that infect mucosal sites – although the magnitude of the serum antibody response depends on the extent of virus replication. Furthermore, live vaccines can induce CTL responses or can prime CTL responses induced during natural infection.

Several vaccines against influenza are licensed for use in humans. Among them, few are administered via the intranasal route. The trivalent Nasalflu Berna vaccine consists of influenza virosomes formulated from inactivated influenza surface glycoproteins, combined with lecithin and heat-labile toxin of *E. coli*. This vaccine has been reported to induce high levels of influenza-specific hemagglutination inhibition IgG and IgA in nasal mucosa and in the saliva. In clinical trials, 85% efficacy was reported in adults and nearly 90% efficacy in children. Although no significant adverse reactions were observed in initial studies, 43 instances of Bell's palsy were encountered among the first season's vaccine recipients (totaling more than 100 000 people). This resulted in suspension of sales and the launch of a detailed investigation of potential side effects.

Another human trial involving influenza vaccine compared intranasal and intramuscular trivalent whole virus vaccines in elderly people, and showed that the intranasal route was significantly more effective in inducing mucosal IgA response. Additionally, combined vaccination involving intramuscular inactivated and intranasal cold-adapted influenza vaccines had significantly increased efficacy in an elderly population. A different human study involving MF59-adjuvanted or nonadjuvanted subunit influenza vaccines indicated that in these trials immune responses, including mucosal IgA production, were not influenced by the presence of adjuvant.

Interesting results were obtained from a mouse study using a peptide mucosal influenza vaccine. A retro–inverso analog, encompassing the protective B-cell epitope sequence from hemagglutinin (HA) (91–108) conjugated to ovalbumin and coadministered with cholera toxin, produced strong systemic (serum IgG) and mucosal (lung IgA) antibody responses that protected against intranasal

challenge with a lethal dose of influenza virus. The half-life of the retro–inverso analog in the presence of lung homogenate proteases was at least 700 times greater than that of the parent L-peptide. These results demonstrated that peptido-mimetic analogs with high resistance to proteolytic degradation are very effective immunogens for intranasal administration.

Existing measles vaccines have been successful in young children when administered as an aerosol or via the intranasal route. However, results from one study did not support these findings and implied that further investigations of the immunization protocol were required.

6 Oral Vaccines

Oral administration of infectious nonpathogenic agents is an ideal method of vaccination, a principal aim being to induce specific mucosal IgA immune responses. An outstanding example of a successful oral vaccine is the Sabin polio vaccine, which induces both local and systemic immune responses and provides good protection against poliovirus infection. Other current oral vaccines include killed whole-cell B subunit and live–attenuated cholera vaccines, live–attenuated typhoid vaccine, and live adenovirus vaccine. Oral immunization with live–attenuated vaccine against adenovirus successfully eliminated frequent epidemics at trainee camps and was in routine use for 25 years in US army recruits. Rotashield was a highly successful live oral vaccine giving good protection against infectious diarrhea, but was withdrawn because of possible links with intussusception. The decision to withdraw vaccination resulted in the reemergence of adenoviral infections and work is now in progress to bring back this effective and safe vaccine.

Oral administration of nonliving antigens can induce oral tolerance to systemic and local autoantigens or allergens, thereby protecting against DTH. This approach could potentially be used to reduce inflammatory reactions in chronic infections, autoimmune disorders, or allergies. However, oral tolerance could hinder successful oral vaccine development, and in practice oral vaccines have proved difficult to develop; therefore, relatively few have been licensed for human use.

7 Conclusions

An important key to the development of novel mucosal vaccines is to understand how mucosal adjuvants can lead to the induction of protective responses (particularly T-cell immunity and local antibody production), while avoiding oral tolerance, induction of regulatory T cells, or immunopathogenic immunity. Genetically engineered live vaccines designed to exploit newly understood immune mechanisms of tolerance and immunoregulation offer fresh hope in the race to develop new mucosal vaccines.

Keywords

Airway Surface Liquid (ASL)
Fluid lining the apical surface of epithelial cells. ASL is depleted in the respiratory tract of CF patients. This increases mucus viscosity and impairs cilia function, resulting in defective mucociliary clearance of bacterial pathogens from CF airways.

Chaperones
Chaperones enable misfolded proteins to be maintained in a conformation that is competent for folding, its subsequent release from the quality control apparatus, and delivery to the cell surface. Certain chemical chaperones, such as phenylbutyrate, CPX, genisteine, and glycerol can increase F508del folding yield in cell culture systems.

Cystic Fibrosis Transmembrane Conductance Regulator (CFTR)
Chloride conducting channel in apical cell membranes. Mutations in CFTR cause the disease cystic fibrosis.

DF508 Mutation
Deletion of phenylalanine in position 508 (F508del) of the CFTR protein; the most common mutation causing CF worldwide. The mutation results in misfolding of the CFTR protein leading to premature intracellular degradation.

Pseudomonas aeruginosa
Most common pathogen in CF lung disease. *Pseudomonas aeruginosa* infection is associated with clinical deterioration and massive endobronchial inflammation in most patients with cystic fibrosis.

Cystic fibrosis (CF) is the most common autosomal recessive disorder in Caucasians, affecting ~1 : 2500 children, with a carrier frequency of 1 : 25. The causative gene, named *CF transmembrane conductance regulator* (*CFTR*), encodes a chloride channel in epithelial cells. Abnormal transport of chloride and sodium ions affects water movement across epithelia, leading to pathophysiological consequences in various organs including the respiratory, gastrointestinal and reproductive tract, the pancreas, and liver. The CF phenotype is rather heterogeneous due to many different mutations in CFTR and the influence of modifier genes. Chronic bacterial lung infections stimulate inflammatory defense mechanisms, leading to extensive tissue remodeling. The resulting emphysema and fibrosis mainly determine the reduced life expectancy in individuals with CF. Owing to improved symptomatic

treatment strategies, including better nutrition and antibiotic therapy, the prognosis of CF individuals has considerably improved and many children now reach adult life. Research is focused on the development of pharmacological drugs correcting ion channel dysfunction, anti-inflammatory drugs and vaccines to prevent airway infections. The causative gene replacement therapy has not yet been successfully applied in CF patients.

1 Epidemiology and Diagnosis

1.1 Incidence and Prevalence

CF (cystic fibrosis) is the most common fatal inherited disease in the Caucasian population, affecting about 1 : 2500 children, with a carrier frequency of 1 : 25. Case-finding studies resulted in incidence rates between 1 : 7700 in Sweden and 1 : 2500 in the United Kingdom. In the United States, an incidence rate of ~1 : 3500 live white births has been estimated and, based on registry data, the prevalence rate in the year 2000 was 8.9 CF patients in 100 000 individuals. Similar prevalence rates have been calculated in Germany (6.9/100 000), Italy (6.5/100 000), and United Kingdom (15/100 000). In other racial groups, CF is much less frequent. Estimates from non-Caucasian populations from the United States give incidence rates of 1 : 14 000 for black Americans and 1 : 11 500 for Hispanic births.

1.2 Diagnosis and Screening

CF is diagnosed on clinical symptoms including persistent cough and diarrhea caused by pancreatic insufficiency. The single most useful diagnostic procedure is the sweat test with chloride concentrations $>60\ \text{mmol}\ \text{L}^{-1}$ in typical cases of CF. Generally, the diagnosis is confirmed by genotyping of the most common CFTR mutations, which vary between different geographic regions. Since CFTR mutations have been identified in persons with clinical conditions such as pancreatitis, infertility due to congenital bilateral absence of the vas deferens (CBAVD), allergic bronchopulmonary aspergillosis, disseminated bronchiectasis, and diffuse panbronchiolitis, it is generally thought that genotype alone is an insufficient basis for the diagnosis of CF.

Fifty percent of all CF patients in the United States are diagnosed by the age of 6 months and 90% by the age of 8 years. Neonatal screening has been recommended because of data revealing that screened patients have better growth and weight gain than controls and that early diagnosis decreases the rate of hospitalization and may lead to an improved lung function in the first 10 years of life. Neonatal screening programs are generally based on a two-step approach with immune reactive trypsinogen in dried blood spots and confirmation by mutation analysis, including multiple CFTR alleles in positive cases. Indeed, neonatal screening has now been established in several countries. It is important to note that clinical benefits from neonatal screening are dependent on adequate treatment, and the failure to provide an adequate standard of care after a diagnosis of CF has been made is probably

a critical factor in outcome. Furthermore, early genetic counseling gives parents the choice of avoiding the birth of another child with CF.

Population screening for CF can be carried out to identify CF carriers or patients, whereas heterozygote screening allows carrier couples to improve family planning. Whether CF carrier screening reduces the number of CF births on a population level is still questionable. Recent guidelines recommend prenatal screening for CF in the United States.

1.3 Prognosis

Prognosis of CF has improved dramatically in some but not all countries as a result of better care and therapy and most children now reach adult life. In the United States, the median age has risen from 8.4 years in 1969 to 14.3 years in 1998 and the median survival rose from 14 years in 1969 to 32.3 years in 1998. Similar improvements in survival have occurred in Europe but significant differences persist because of differences in treatment strategies, access to specialized CF centers, and socioeconomic status. It is generally agreed that patients treated in a CF center with specialized medical care have a better survival. Since chronic lung disease contributes mostly to morbidity and mortality in CF, optimal antibiotic therapy may influence prognosis considerably. Patients with class IV or V mutations associated with residual CFTR function have better clinical outcomes compared to those with class II mutations (including F508del, see below). However, for most patients, prognosis cannot be determined on the basis of genotype analysis.

2 Genetics and Functions of CFTR

2.1 CFTR, Mutations, Genotype-phenotype Relations and Modifier Genes

CF is caused by mutations in a 230-kb gene on chromosome 7, encoding a 1480 amino acid polypeptide named *cystic fibrosis transmembrane conductance regulator* (*CFTR*). Over 1200 mutations and sequence variants have been described to date and reported to the Cystic Fibrosis Genetic Analysis Consortium. Most of these mutations are rare and only 4 mutations occur in a frequency of more than 1%. CFTR mutations are grouped into five classes: defective synthesis (I), defective processing (II), defective regulation (III), defective conductance (IV), and partially defective production or processing (V). Class I–III mutations are more common and are associated with pancreatic insufficiency. Patients with the rarer class IV–V mutations often are pancreatic sufficient. The most common mutation worldwide is a class II mutation caused by a deletion of phenylalanine in position 508 (F508del) of the CFTR protein, leading to misfolding. Of the 43 849 CF chromosomes tested, 66% are F508del. Linking mutations to the severity of lung disease has been unsuccessful, and patients who are homozygous for the F508del mutation exhibit a wide spectrum in the rate of development and severity of lung disease.

Because F508del homozygous patients differ largely in phenotype and in chloride conductance, it is believed that environmental factors and/or genes other than CFTR modify the development, progression, and disease severity of CF. At present, a number of candidate genes including genes that regulate aspects of innate

lung defense and inflammatory cascades have been suggested, which await confirmation in large CF population studies. Modifier genes are now being identified using single nucleotide polymorphisms in genome-wide searches and complemented by proteomic approaches. Modifying genes are likely to affect many different aspects of the CF phenotype, which therefore remains difficult to predict from CFTR mutation data alone.

2.2 CFTR Function and Structure

CFTR functions as a chloride channel in apical membranes. The primary structure of CFTR indicated that it belongs to a family of transmembrane proteins called *ATP-binding cassette* (*ABC*) *transporters*. ABC transporters (or traffic ATPases) form a large family of proteins responsible for the translocation of a variety of compounds across membranes of both prokaryotes and eukaryotes. CFTR is composed of five domains: two membrane-spanning domains (MSDs), two nucleotide binding domains (NBDs), and a regulatory (R) domain (Fig. 1). The F508del mutation occurs in the DNA sequence that codes for the NBD1. In wild-type CFTR, an extracellular glycosylation site is present and the NBDs and R domain are located on the intracellular side of the membrane.

CFTR channel activity is controlled by the balance of kinase and phosphatase activity within the cell and by cellular ATP levels. Activation of a cAMP-dependent protein kinase (PK) (such as PKA and PKC) causes the phosphorylation of multiple serine residues within the R domain. Once the R domain is phosphorylated, channel gating is regulated by a cycle of ATP binding and hydrolysis at the NBDs, which form a head-to-tail dimer. The two NBDs are nonequivalent in their interactions with nucleotides. Whereas NBD1 acts as a site of stable nucleotide interaction, NBD2 constitutes a site of fast turnover. Finally, protein phosphatases dephosphorylate the regulatory domain and return the channel to its quiescent state. It has been proposed that energy from ATP hydrolysis by the conserved NBDs causes conformational changes in the MSDs, which are coupled with the opening and closing of the pore. The

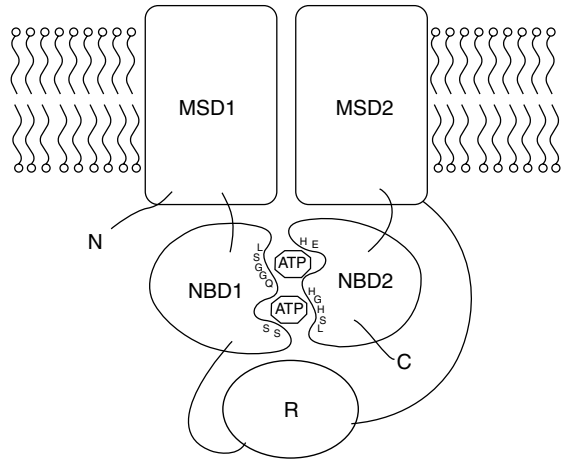

Fig. 1 Schematic model of CFTR. MSD: membrane-spanning domain, NBD: nucleotide binding domain; R: regulatory domain. Also indicated is a putative nucleotide binding domain. (From Lewis, H.A. et al. (2004) Structure of nucleotide-binding domain 1 of the cystic fibrosis transmembrane conductance regulator, *EMBO J*. **23**, 282–93).

sixth transmembrane segment seems to play a dominant role in determining the pore properties of CFTR. The CFTR pore has a deep wide intracellular vestibule but a shallow wide extracellular vestibule. The resolution of the crystal structure of mouse NBD1 confirms some of these notions (Fig. 2). This NBD1 differs from typical ABC domains in having added regulatory segments, a foreshortened subdomain interconnection, and unusual nucleotide conformation and undetectable ATPase activity.

The complex secondary structure of the protein suggests that CFTR possesses other functions in addition to being a chloride channel. Amongst others, CFTR has been described as a regulator of other apical membrane conductance pathways through interactions with the amiloride-sensitive epithelial sodium channel and the outwardly rectifying chloride channel. Whether the activity of the epithelial sodium channel (ENaC) is inversely related to the activity of CFTR or whether its activity increases with CFTR activity is not clear at present. ENaC is also regulated by the serum and glucocorticoid-dependent kinase (SGK1), which is increased in CF lung tissue because of inflammatory processes. F508del CFTR has defects in both channel gating and endoplasmic reticulum-to-plasma membrane processing. Recent data suggest that CFTR also transports HCO_3^- as well as glutathione or regulates HCO_3^- transport through epithelial cells.

2.3 CFTR Trafficking and Tissue Location

F508del is retained in the endoplasmic reticulum (ER) because of improper folding and, therefore, will not reach the Golgi

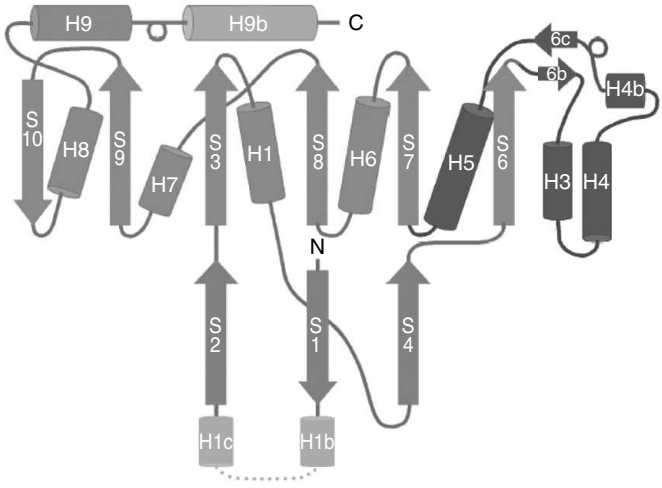

Fig. 2 Topology diagram of mNBD1. The F1-type ATP-binding core subdomain is shown in gold, the ABC α-subdomain in cyan, and the ABC ß-subdomain in green. Regions of mNBD1 that are different from previous ABC structures are shown in gray. Circles indicate the positions of 3_{10} helices. (From Lewis, H.A. et al. (2004) Structure of nucleotide-binding domain 1 of the cystic fibrosis transmembrane conductance regulator. *EMBO J.*, **23**, 282–293) (see color plate p. xxiv).

complex for the acquisition of complex N-linked oligosaccharide chains, important in the quality control pathway to prevent the development of improperly folded glycoproteins. Thus, the F508del mutation is primarily a protein-folding defect with altered protein trafficking or kinesis secondary to altered folding. Although some F508del can be delivered to the plasma membrane, channel gating is profoundly defective, because PKA-dependent phosphorylation of the R domain activates F508del CFTR to a much lesser degree than wild-type CFTR. Like other membrane glycoproteins, CFTR interacts with chaperone proteins, which prevent premature and inappropriate folding interactions during biosynthesis and increase the overall yield of correctly folded product. In this context, hsp70, hsc70, and calnexin have been identified. CFTR has also been shown to form a macromolecular complex in apical membranes with the ß2 adrenergic receptor and the ezrin-/radixin-/moesin-binding phosphoprotein 50. The assembly of the complex is regulated by PKA-dependent phosphorylation and deletion of the regulatory domain of CFTR abolishes PKA regulation of complex assembly.

In general, CFTR is found in tissues that are clinically affected by CF although low levels also occur elsewhere. The most common site is in the apical membrane of epithelial cells that line exocrine ducts or airways, and this is consistent with the proposed chloride channel function. By immunohistochemistry, wild type but not F508del CFTR was detected at the luminal membrane of crypt colonocytes, sweat glands, and respiratory epithelial cells. Both B and T lymphocytes express CFTR, reveal abnormal chloride transport, although this seems to have little functional importance. No important functional abnormalities have been shown in the heart or the placenta, both sites of CFTR expression, and the electrolytes of ocular humor, breast milk, and seminal fluid are not significantly altered in CF.

3 Basic Defect-pathology Relations

CF leads to pathologic changes in organs that express CFTR; therefore, secretory cells, sinuses, lungs, pancreas, liver, and reproductive tract are involved. The most dramatic changes are observed in CF airways where the basic defect causes mucus retention, chronic bacterial infection, and inflammation.

3.1 Respiratory Tract

Lung infections with *Pseudomonas aeruginosa* constitute a predominant disease phenotype in CF patients. Infections with *Staphylococcus aureus* and *Haemophilus influenzae* are also frequent. Several hypotheses have been offered to explain the failure of mucosal defense and the high prevalence of *P. aeruginosa* in the CF lung. It has been proposed that *P. aeruginosa* binds to CF airway epithelial cell membranes in higher density than to respective cells from normal individuals owing to an increased *P. aeruginosa* asialo-GM1 receptor density. The higher bacterial number would then lead to infection in CF airways. Alternatively, wild-type CFTR (but not mutated CFTR) has also been shown to be a receptor for *P. aeruginosa*, which mediates bacterial cell internalization and *P. aeruginosa* killing. In CF airways, therefore, *P. aeruginosa* would not be eradicated intracellularly

and could multiply and cause infection. Other studies, however, reveal that both *P. aeruginosa* and *S. aureus* are located in the mucus layer on respiratory epithelial cells rather than directly on cell membranes and that no difference in location and number of adhering bacteria is visible regardless of whether normal or CF primary respiratory cells are used or infected CF lung tissue is investigated for *P. aeruginosa* or *S. aureus* adhesion. Additionally, on the basis of the assumption of an increased sodium chloride concentration due to a defective CFTR channel on the luminal side of the respiratory epithelium, it has furthermore been suggested that salt-sensitive cationic antimicrobial peptides (defensins) are inactivated in the airway surface liquid (ASL) of CF patients, which would lead to bacterial multiplication and subsequent infection. However, not all defensins are salt sensitive and it has been difficult to prove that the ASL in CF is indeed hypertonic.

In contrast, most *in vivo* data reveal that the ASL from normal and CF individuals is isotonic. This notion has been explained by a mechanism whereby the airway epithelium reduces its volume in order to reach isotonicity (Fig. 3).

Owing to defective chloride secretion of the CF respiratory epithelial cells, sodium and therefore also water are excessively reabsorbed from the periciliary liquid, which reduced the volume of the ASL from ~20 to 6 μm. Consequently, mucus viscosity is increased and cilia function is impaired, which leads to a defect in mucociliary clearance of bacterial pathogens from CF airways. Bacteria invading the CF lung are trapped in this viscous mucus layer on top of respiratory epithelial cells, where they encounter microaerophilic or anaerobic growth conditions due to abnormal oxygen consumption of the CF cell. The physical conditions in the viscous matrix trigger a switch of *S. aureus* and *P. aeruginosa* from nonmucoid to mucoid cell types, the predominant bacterial phenotype in CF lungs. Apparently, the size of the mucoid bacterial microcolonies impairs phagocytosis and eradication of the pathogens by phagocytis cells and thus is thought to be one important factor in the pathogenicity of lung disease. The anaerobic viscous environment on the respiratory epithelial mucus layer, which is also present in large mucus (sputum) plugs later in the course of the infection, is the main reason for the chronicity of the bacterial lung infection and inflammation in CF lungs (see below).

3.2 Other Organs

Water retention as a consequence of defective chloride secretion and excessive sodium absorption is also the explanation for the pathophysiologic events in the pancreas of CF patients, leading to exocrine pancreatic insufficiency in approximately 90% of CF patients. Without sufficient fluid and HCO_3^-, digestive proenzymes are retained in pancreatic ducts and prematurely activated, which ultimately leads to tissue destruction and fibrosis. As a consequence of increasing Langerhans cell destruction, insulin secretion is decreased and delayed in older CF patients, leading to increasing prevalence of both type I and II diabetes. The consequences of CFTR mutations also lead to abnormal liver function in at least one-third of patients and biliary cirrhosis in less than 10% of the patients. Ninety-eight percent of males with CF are infertile, with aspermia secondary to atretic or absent vasa deferentia and dilated or absent seminal vesicles. Sexual potency

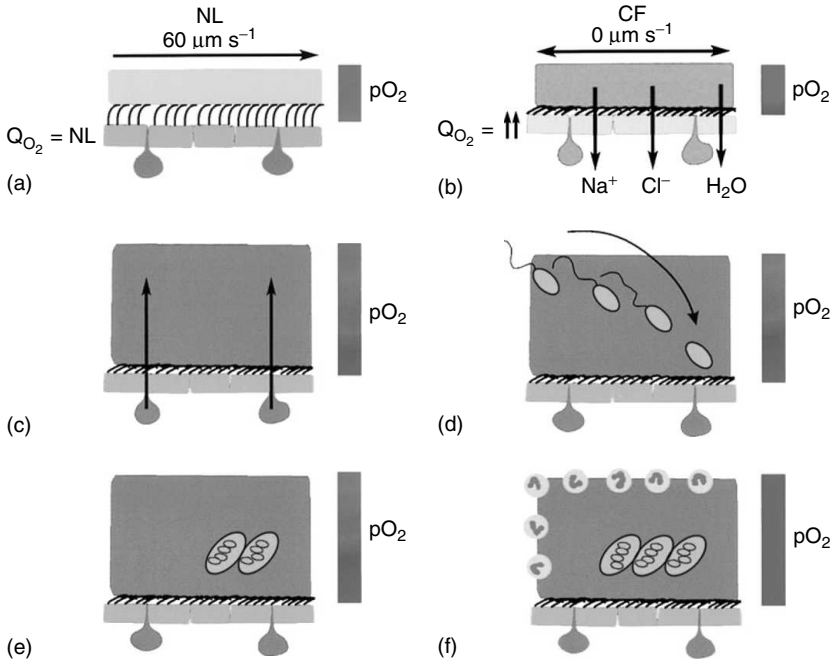

Fig. 3 Schematic model of the pathogenic events hypothesized to lead to chronic *P. aeruginosa* infection in airways of CF patients. (a) On normal airway epithelia, a thin mucus layer (light green) resides atop the PCL (clear). The presence of the low-viscosity PCL facilitates efficient mucociliary clearance (denoted by vector). A normal rate of epithelial O_2 consumption (Q_{O2}; left) produces no O_2 gradients within this thin ASL (denoted by red bar). (b–f) CF airway epithelia. (b) Excessive CF volume depletion (denoted by vertical arrows) removes the PCL, mucus becomes adherent to epithelial surfaces, and mucus transport slows/stops (bidirectional vector). The raised O_2 consumption (left) associated with accelerated CF ion transport does not generate gradients in thin films of ASL. (c) Persistent mucus hypersecretion (denoted as mucus secretory gland/goblet cell units; dark green) with time increases the height of luminal mucus masses/plugs. The raised CF epithelial Q_{O2} generates steep hypoxic gradients (blue color in bar) in thickened mucus masses. (d) *P. aeruginosa* bacteria deposited on mucus surfaces penetrate actively and/or passively (due to mucus turbulence) into hypoxic zones within the mucus masses. (e) *P. aeruginosa* adapts to hypoxic niches within mucus masses with increased alginate formation and the creation of macrocolonies. (f) Macrocolonies resist secondary defenses, including neutrophils, setting the stage for chronic infection. The presence of increased macrocolony density and, to a lesser extent neutrophils, render the now mucopurulent mass hypoxic (blue bar) (From Worlitzsch, D., Tarran, R., Ulrich, M. et al(2002) Effects of reduced mucus oxygen concentration in airway Pseudomonas infections of cystic fibrosis patients, *J. Clin. Invest.* **109**, 317–325) (see color plate p. xxiv).

as well as spermatogenesis are normal, and CF males have become fathers with techniques such as microscopic epididymal sperm aspiration and intracytoplasmatic sperm injection. Female reproductive function is normal, although cervical mucus has been reported to be dehydrated, which may impair fertility.

4
Immunology of Chronic Respiratory Infections

The inability of the immune defense system to keep the airways free of bacteria led to speculations that the then unknown genetic abnormality causes an immunological defect. With the knowledge that the CF gene codes for an epithelial ion-transport protein and data showing essentially normal systemic immune function in CF, the immunology of CF was then regarded no differently from the immunology of any other chronic infection. However, currently, CF lung disease is thought to result from a defect in innate immune response that leads to chronic lung infection (see above) and chronic inflammation. The question of whether the consequences of the basic defect provoke abnormal respiratory inflammation without prior bacterial stimuli has not been resolved as yet.

4.1
Type III Hypersensitivity Reaction

CF patients respond with the production of antibodies to a large number of *P. aeruginosa* antigens and antigens of other microbial pathogens. Antibody production provokes hypergammaglobulinaemia in infected CF patients, and leads to immune complexes, which are detectable in patients' sputa, bronchial secretions, or serum samples. Immune complexes stimulate the major phagocytic cell entering the endobronchial airways, the polymorphonuclear leukocytes (neutrophils). High immune complex levels (and antibody titers) correlate with poor clinical status of the patients, suggesting that neutrophil stimulation is responsible for tissue damage or remodeling in CF airways. Nevertheless, some of the antipseudomonal antibodies are nonopsonic or even blocking phagocytosis, particularly antibodies directed against *P. aeruginosa* polysaccharide components. This phenomenon has not yet been fully explained and might be related to a subsequent loss of avidity in antigen binding during the chronic course of the infection. During this type III hypersensitivity reaction, neutrophils are attracted from the blood vessels to the site of infection by chemoattractants, includingleukotriene B_4 (LTB_4) and interleukin (IL)-8.

As mentioned above, bacterial microcolony formation triggered by the anaerobic viscous environment on the respiratory epithelial mucus layer and in the large mucus (sputum) plugs (Fig. 4) is one reason for the chronicity of the bacterial lung infection. In addition, other factors may be involved. The highly viscous mucus may affect the motility of neutrophils, resulting in retarded neutrophil transmigration of the mucus layer overlaying the epithelial cells in CF airways, which could give bacteria a temporal advantage to form their protecting microcolony polysaccharide coat. Owing to the anaerobic environment in the viscous mucus, antimicrobial activity of neutrophils related to the production of reactive oxygen species is impaired and bacteria with intrinsic or acquired resistance to antimicrobial peptides (defensins) may survive phagocytosis under these circumstances. All three conditions may be present at the same time in infected CF mucus and lead to chronicity of the infection characterized by large volumes of necrotic neutrophils and accumulation of polymerized DNA strands that form highly viscous sputum plugs (Fig. 4).

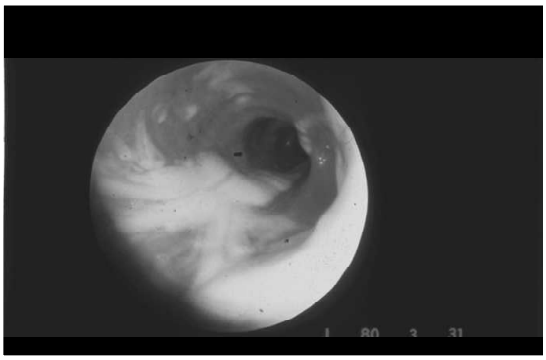

Fig. 4 Mucus plugs obstructing CF airways consisting of mostly necrotic neutrophils and bacterial microcolonies. By courtesy of Dr. Uschi Weber, Wangen im Allgäu, Germany.

The anaerobic nature of the mucus plugs obstructing airways of CF patients implies that lysosomal enzymes for neutrophils such as elastase rather than reactive oxygen species play a major role in the pathophysiology of endobronchial inflammation. Neutrophil elastase cleaves a variety of substrates including the endogenous serine proteinase inhibitors α_1-proteinase inhibitor (α_1-PI) and secretory leukocyte proteinase inhibitor (SLPI), the structural components or airways and alveoli, elastin, and proteins of the innate and specific immune systems such as immunoglobulines, immune complexes, complement components, and cell surface receptors on neutrophils or lymphocytes. Since neutrophil-mediated phagocytosis is dependent on intact complement receptors (CR1, CR3), complement components (C3b, C3bi) and intact, opsonic antibodies, opsonophagocytosis is heavily impaired in plugs in the CF lung. On the other hand, neutrophil elastase may act as a regulatory enzyme in chronic inflammation by lowering signal transduction between inflammatory molecules and effector cells. Thus, the impairment of opsonophagocytosis and T cell function by neutrophil serine proteases may have beneficial and deleterious consequences for the host: temporal down-regulation of inflammation on the one hand and allowance of bacterial survival on the other hand. Similarly, stimulation of airway gland secretion by neutrophil serine proteases may be seen as beneficial and deleterious for the host. Mucus hypersecretion may be regarded as beneficial, because it removes bacterial pathogens from close contact with airway epithelial cells into the airway lumen, and deleterious because airway obstruction leads to lung function impairment.

Besides neutrophil serine proteases, macrophage-derived metalloproteinase and metalloproteinases from neutrophils including neutrophil gelatinase (type IV collagenase) may contribute to tissue remodeling in CF airways, particularly in the alveoli.

Despite the wealth of information on the neutrophil-dominated pathophysiology of CF lung disease, little is known about how endobronchial infection/inflammation impacts on fibrosis and emphysema in the alveolar space of CF patients.

4.2 Cytokines, Growth Hormones, and Nitric Oxide (NO)

The inflammatory system communicates by a large repertoire of chemical

messengers called *cytokines* produced by epithelial cells, T lymphocytes and phagocytic cells. In bronchoalveolar lavage (BAL) samples of CF patients, increased proinflammatory cytokine levels including TNFα, IL-6, and IL-8 have been measured. Persistent high cytokine levels may have deleterious consequences. For example, TNFα may cause cachexia and osteoporosis, and IL-8, a chemotactic attractant for neutrophils, may lead to a ''self-perpetuating'' inflammatory process. Furthermore, BAL fluids from CF patients contain significantly less IL-10 than BAL from normal control individuals, suggesting an imbalance between upregulating and downregulating cytokines during chronic inflammation. Besides cytokines, growth factors such as insulinlike growth factor 1 (IGF-1), which can be produced by many cell types including lymphocytes and alveolar macrophages may contribute to lung pathology in CF patients. One of the consequences of enhanced IGF-1 production is fibrosis.

NO originates from the biotransformation of L-arginine to L-citrulline by enzymes called *NO synthases* (*NOS*). Although one would expect that NO production is increased in CF due to chronic lung inflammation, this is not the case and NO levels in exhalations of CF patients are low. This phenomenon has not been completely resolved and attributed in part to low levels of the inducible isoform of NOS (iNOS) in the respiratory epithelium of CF patients and consumption of NO in airway secretions in CF airways during inflammation. Since NO has multiple functions (e.g. bronchodilation, phagocytic killing of bacteria, stimulation of ciliary function), low NO concentrations in airways of CF patients may be of pathophysiologic relevance.

5
Causative and Symptomatic Therapy Strategies

5.1
Gene Replacement Therapy

The ultimate curative treatment for CF is to restore CFTR function by transfecting CF cells with wild-type CFTR. Since the initiation of the first clinical trials for CF lung disease using recombinant adenovirus in the early 1990s, the field has encountered numerous obstacles including (1) difficulties with vector production, (2) inefficient delivery of vector, and (3) vector-induced inflammation. Over 30 trials on CFTR gene therapy, mainly using adenoviral vectors or liposomes have been published and have established the proof of principle for gene transfer to the lung. However, efficiency is generally low. Viral vectors have encountered the problem of host response to the vector that either results in mucosal inflammation or inefficiency of gene transfer on repeat dosing. Despite these obstacles, several research groups are currently involved in preclinical and clinical studies to enhance the efficiency and selectivity of gene delivery to the lung.

5.2
Pharmacological Treatment of CFTR

The intracellular production, trafficking or activation of CFTR are possible targets of therapeutic interventions. Class I mutations lead to decreased production of CFTR mRNA and gentamicin has been shown to partially overcome this problem. The frequency of the F508del allele among CF patients and the possibility that chloride channel activity can be restored in these

patients suggest strategies for CF treatment based on increasing the efficiency of folding and intracellular processing of this mutant. Loss of this amino acid decreases the efficiency of folding of NBF1 *in vitro* and appears to increase the probability that nascent CFTR chains become committed to degradation by a pathway that involves at least in part the ubiquitin/proteosome pathway. Certain chemical chaperones, such as phenylbutyrate, CPX, genisteine, and glycerol can increase F508del folding yield, possibly by stabilizing an early intermediate in CFTR folding, maintaining it in a conformation that is competent for folding and its subsequent release from the quality control apparatus and delivery to the cell surface. Moreover, 4-phenylbutyric acid has also been shown *in vitro* to increase production of mature CFTR and chloride transport at the cell surface, most likely by a mechanism involving upregulation at the transcriptional level and modulation of protein-folding steps. Other agents enhance the activity of F508del CFTR chloride channels at the cell surface. The best studied of these agents is the flavonoid genistein, which interacts directly with NBD2, to stabilize the open-channel configuration. Agents termed *pharmacological chaperones* (e.g. MPB compounds) potentiate the activity of mutant chloride channels present at the cell surface and rescue the cell surface expression of the same mutants. High-throughput screening technology is currently being used in the search for further compounds that either rescue the cell surface expression of mutant CFTR (termed *CFTR correctors*) or enhance the activity of mutant chloride channels present at the cell surface (termed *CFTR potentiators*). Vitamin C has been shown to regulate CFTR-mediated Cl secretion in epithelia and, therefore, represents a potential drug in CF. Furthermore, curcumin, a Ca-adenosine triphosphatase pump inhibitor, corrected defective nasal potential difference in F508del CFTR mice.

Whether treatment with chaperones will result in sufficient concentrations of CFTR on the cell surface of epithelial cells to improve CF related pathology is unclear at present. Furthermore, mutated CFTR that reaches the cell membrane may fail to function normally. Additional targets of CFTR pharmacotherapy include activators of chloride secretion such as UTP or inhibitors of sodium absorption such as amiloride. Both drugs have a very short half-life, limiting their efficacy, but newer compounds with an improved pharmacokinetic profile are being tested in CF trials. A double-blind phase II inhalation study of the UTP analog INS37217 in patients with mild CF lung disease was safe and resulted in significantly better FEV1, FEF 25 – to 75%, and FVC in the treatment group compared to patients receiving placebo. INS37217 is believed to enhance the lung's mucosal hydration and mucociliary clearance mechanisms by activating an alternative ion channel that acts in the same way as the defective ion channel in moving salt and water to the surface of the airways. Similarly, hypertonic saline is mechanistically active and early trials show beneficial results. Thus, the notion that getting water to the surface of the respiratory epithelium of CF patients will correct the pathological consequences of the basic defect becomes more and more realistic.

5.3 Prevention of Infection

Prevention of bacterial lung infection is regarded as the primary aim for

CF. Epidemiological studies suggest that transmission of *P. aeruginosa* and other pathogens occurs either by direct patient-to-patient contacts or from various environmental bacterial reservoirs. Improved hygienic measures and separation regimes have therefore been implemented in several CF centers to limit cross-infection. Prevention of *P. aeruginosa* lung infection by active vaccination may also represent a suitable alternative strategy in CF. Whereas studies using *P. aeruginosa* lipopolysaccharide preparations were unsuccessful, a small open vaccine trial using a polysaccharide-exotoxin A conjugate as antigen showed promising results. Currently, phase III multicenter vaccine trials using a *P. aeruginosa* flagella vaccine and the polysaccharide-exotoxin A conjugate vaccine are underway in Europe.

5.4 Treatment of Infection

Improved antibiotic therapy strategies against respiratory tract infections are considered as the main reason for the increased life expectancy of CF patients that has been achieved over the last decades. Antibiotics are administered by the intravenous, aerosol, or oral route, and treatment strategies include regular courses independent of the clinical status of the patient or restricted to episodes of acute exacerbations. Decisions about optimal antibiotic therapy regimes are difficult to take since eradication of the bacteria is not normally achieved. Owing to poor penetration of antibiotics into the anaerobic sputum plugs and the rapid development of mutator strains that display increased resistance against antimicrobial drugs, even with intensive antibiotic regimens, mucoid *P. aeruginosa* cannot be eradicated. A major improvement in the strategy to fight pulmonary *P. aeruginosa* infection in CF patients is early antibiotic therapy. Anti-staphylococcal treatment for at least two weeks results in an eradication rate of ~75% and only a low rate of patients harbor *S. aureus* for more than six months thereafter. In the early phase of *P. aeruginosa* colonization, antibiotic therapy may avoid the shift to chronic mucoid *P. aeruginosa* infection. The combination of inhaled colistin with oral ciprofloxacin, inhaled colistin or inhaled tobramycin alone has been used to treat early *P. aeruginosa* colonization. Long-term follow-up of patients treated with inhaled tobramycin following initial colonization with *P. aeruginosa* demonstrated that treatment not only postponed chronic infection but also led to eradication of the bacteria in treated patients. This treatment regime will most probably reduce the incidence of chronic airway infection with *P. aeruginosa* in CF patients.

5.5 Anti-inflammatory and Mucolytic Drugs

Since chronic inflammation is the cause of tissue remodeling and destruction in CF airways, the administration of anti-inflammatory drugs to other treatment arms is a logical strategy. High-dose prednisone was found to reduce the decline of lung function for the first two years in *P. aeruginosa* positive patients, but serious side effects such as growth retardation, glucose intolerance, and cataracts were found in treated patients. Therefore, the risk/benefit ratio does not favor long-term prednisone therapy in CF patients. Treatment with inhaled steroids did not result in clear benefits for pulmonary function in CF patients. High-dose ibuprofen slowed the lung function decline in CF patients, but the beneficial effect was concentrated

to a subgroup of patients aged 5 to 13 years. Increasing antiproteinase levels in the lung by supplementation with suitable inhibitors has been proposed. However, neither aerosolized recombinant human secretory leukocyte proteinase inhibitor (rSLPI) nor aerosolized α_1-PI has been tested in large numbers of CF patients. A multicenter trail with a small neutrophil elastase inhibitor, EPI-hNE4 is currently carried out in CF patients. Recombinant human DNase has been found to reduce sputum viscosity, improve pulmonary function, and reduce the number of pulmonary exacerbation in CF patients with moderate and mild lung disease. Lipoxins are anti-inflammatory lipid mediators that modulate neutrophilic inflammation. Furthermore, administration of a metabolically stable lipoxin analog to infected and inflamed murine lungs suppressed neutrophilic inflammation, decreased pulmonary bacterial burden, and attenuated disease severity, suggesting that lipoxins have therapeutic potential in CF.

5.6 Transplantation

Double lung or heart lung transplantation is a therapeutic option for CF patients with end-stage lung disease. Overall survival of lung transplant patients is poorer compared to other organ transplantation with a three-year survival of approximately 60% in CF patients. Generally, survival is better for adults than for children, but individual centers have reported a survival benefit through lung transplantation in children.

5.7 Treatment of Pancreatic Insufficiency, Nutrition, and Liver Disease

CF patients with poor nutritional status are more prone to chest infections and patients with normal fat absorption have a better pulmonary prognosis. Poor nutritional status has been linked to worse prognosis of CF patients, a finding that has prompted an aggressive approach of maintaining normal weight in CF patients. The introduction of acid-resistant microspheric pancreatic enzyme preparations in the 1970s has greatly improved but not normalized the weight of CF patients, and a European consensus was reached on optimized nutrition in CF. Unfortunately, both oral caloric supplements and enteral feeding by either nasogastric tube or gastrostomy tube have been introduced clinically prior to performing adequate scientific studies. Ursodeoxycholic acid has been shown to normalize elevated liver enzyme levels, but its long-term effect on the evolution of liver disease remains largely unproven. Liver disease is a life-limiting factor in only a few patients, but liver transplantation has been successfully performed in individual CF patients with advanced liver and limited pulmonary disease.

5.8 Animal Models

The possibility to directly modify CFTR in experimental animals by molecular techniques allows insight into the physiologic functions of CFTR and its malfunction in the course of CF. Several CFTR mouse models have been constructed. However, owing to differences in gland distribution between man and mouse, the most important trait of CF, chronic pulmonary infection, has not been reproduced in these animal models. One mouse strain has recently been shown to exhibit pathologic alterations in all organs typically affected in CF, but the pulmonary phenotype lacks chronic infection and inflammation. However, on

the basis of the hypothesis that mutations in the CFTR gene result in increased airway sodium absorption, mice were generated with airway-specific overexpression of ENaC. Indeed, these mice revealed ASL volume depletion, increased mucus production, delayed mucus transport, and mucus adhesion to airway surfaces. Furthermore, defective mucus transport caused a severe spontaneous lung disease, sharing features with CF, including mucus obstruction, goblet cell metaplasia, neutrophilic inflammation, and poorer bacterial clearance. However, the chronic type of infection as seen in CF patients was not observed. Other approaches to study particularly CF lung pathophysiology are based on human tracheal xenografts in immunodeficient severe combined immunodeficiency (SCID) mice and nude mice.

Keywords

Aneuploidy
A cell containing other than the normal diploid number of chromosomes.

Arbitrarily primed PCR and Inter-(Simple Sequence Repeat) PCR
Sampling methods to monitor genomic damage, in which polymerase chain reaction products are compared for tumor and corresponding normal tissue DNA. The former method utilizes arbitrary PCR primer pairs to copy the sampled set, while the latter method utilizes a single PCR primer to copy sequences (200–2000 bp) between relatively closely spaced repeat sites.

Intrachromosomal Instability
A form of genomic instability in which alterations occur within individual chromosomes, but not particularly to repeat sequences.

Microsatellite Instability
A form of genomic instability arising from defects in the DNA mismatch repair system, leading particularly to alterations of small numbers of bases within DNA-repeat sequences.

Spectral Karyotype (SKY)
A technique by which individual chromosomes are labeled with distinctive fluorescent probes, enabling the direct viewing of both the number of chromosomes in a cell and the translocations between chromosomes.

Genomic instability is a widespread and essential feature of the common adult-onset cancers. For solid tumors to arise, several key genes must become mutated (to generate growth, facilitate invasion, enlist nutrient supply, evade the immune response, avoid apoptosis, and so on) and this degree of mutation requires abnormally high mutation rates. To achieve such rates, genes whose normal role is to maintain genomic integrity become mutated, leading to ongoing genomic instability. Exogenous mutagens (carcinogens) additionally contribute to overall genomic damage, particularly in tobacco smokers. Genomic destabilization slowly leads to cancer as cells with mutations in genes advantageous for tumor development become selected, expand their populations, and evolve further. A considerable majority of human genes are involved in multicellular coordination and are not essential for maintaining the viability and reproductive potential of individual cells; thus, a window exists wherein an appropriate degree of genomic instability leads to tumor progression, as somatic evolution selects cells driven by self-interest. As with Darwinian evolution, such somatic evolution inherently leads to genomic diversity,

seen clinically as tumor heterogeneity. Although genomic instability and the ensuing genomic heterogeneity render therapeutic targeting difficult, measurement of the degree and form of genomic instability has considerable potential as a clinical prognostic tool.

1
The Need for Genomic Instability

1.1
The Conceptual Framework

Cancer. What a strange disease! For in biology we are so used to seeing order, stepwise differentiation and development, and precise control. Yet, with the common adult-onset solid tumors, we see imprecision, unpredictable behavior, evasion of targeted therapies, disorganized growth, and chaos. And death. But why is this so? What is the nature of this disease, and why does it not behave like other life? Or does it, and we just need to recognize that cancer has more in common with the random nature of evolutionary biology than it does with the fine coordination of organismic biology governed by precise processes of molecular biology?

To comprehend these cancers, we must first recognize the basic nature of multicellular organisms such as ourselves. Going from a unicellular organism to a multicellular organism was a huge leap in evolutionary history. Single-celled organisms have to cope with the formidable tasks of creating and replicating genetic information, controlling its expression, metabolically capturing energy to synthesize new components, and then coordinating the whole process to replicate their entire selves. These cells have the essential genes and systems to allow self-replication, but their only concern about their neighbors is to outcompete them. In contrast, for complex multicellular organisms like ourselves, with a wide variety of highly differentiated specialized tissues, spatial and temporal control and coordination issues come to predominate. Over the course of our evolutionary history, genes evolved, which enable cells to communicate with one another, responding to signals from other cells in a highly specific manner, while also enabling those same cells to respond to other programs locked in during differentiation. Our cells must cooperate, proliferating only when and where appropriate, and willingly dying when and where appropriate; the necessary genes to effect these behaviors evolved. Further gene-based regulatory mechanisms arose, which cause specific cells to adhere only to appropriate partners, and move only in appropriate manners.

The intricate, evolved coordination process generating this complex cellular behavior is contained within the information stored in each duplicated copy of our genome, present in each of our hundred trillion or so cells, and this coordination process continues, as most of these cells are themselves turning over, at widely varied rates. The complexities of this coordination process are far more intricate than those fundamentally required for unicellular life, and this is manifested within our genomes. For the unicellular eukaryote yeast, only about 4000 genes are essential for its cellular growth and replication (Saccharomyces Genome Database). In contrast, humans contain approximately

10 times as many genes; some of these additional genes generate more complex cellular structures and functions, but most are utilized to coordinate multicellular growth and organization, giving rise to differentiated cells and tissues signaling and responding to one another.

What happens when the quality of a cell's genetic information deteriorates? When damage is severe and extensive, essential gene functions will be lost and the cell dies. But when genetic damage is less severe, and is ongoing over a long period of time, cancer can slowly arise. For if genetic damage occurs at a rate insufficient to kill a cell, a population of mutant cells has time to develop, expand, and acquire additional mutations. With most human genes involved in multicellular coordination, it becomes substantially more likely that a coordination gene will be lost than a gene essential for cellular survival. If both alleles of a gene eventually become lost or mutated, less coordinated growth then occurs. And these daughter cells in turn evolve further, and expand their populations. Selection will occur again and again for cells with greater abilities to proliferate, spread, and evade attack in the form of host defenses or therapeutic treatments. Different daughter cells are free to evolve in different directions; unlike classical Darwinian evolution where natural selection is stringent and competition fierce, the human body is a hospitable environment for many of the successful diverging lineages. This somatically evolved, genomically heterogeneous cell population becomes what we see clinically presenting in the patient as a cancer.

Human evolution occurred in spite of this same basic problem inherent in all multicellular organisms, namely, where loss of genomic stability will lead to cells evolving toward unicellular behavior patterns, with disastrous consequences. We therefore contain within each cell a series of redundant safeguards necessary to maintain the quality of our genetic information for many decades, enabling us to survive as individuals to a point where our progeny are fully capable of surviving and reproducing on their own. If a single gene were sufficient to start the process of somatic evolution eventually leading to malignancy, then somewhere within our large population of cells that individual gene loss would inevitably occur, and we would never be able to survive to adulthood. Redundant safeguards to ensure replication fidelity and efficient damage repair therefore exist to preserve our genomic integrity. Additional apoptotic safeguards destroy cells with badly damaged genomes, reducing the probability of developing cancer to a tolerable level. In spite of this, the disease manages to eventually develop clinically in about one-fourth of us, and is present in nearly all the elderly at a microscopic level. Low mutation rates acting over a long period of time provide a powerful means for even the most stringent safeguards to be overcome by natural selection and cell lineage expansion.

1.2 Multiple Forms of Genomic Damage

Unlike leukemias where a single translocation can complete the two basic steps needed to produce this malignancy, solid tumors require several mutational events before a normal cell becomes an uncontrollably proliferating invasive cancer cell; as described above, this slowly develops through an ongoing process of cell population expansion and natural selection of advantageous mutations. To a large degree, this arises from the mutation of

genes whose role is for the maintenance of genomic integrity, yielding the genomic instability that underlies tumor progression; the continuing genomic instability of cultured tumor cells conclusively establishes a genetic component. Extrinsic carcinogens such as tobacco smoke can initiate the process by mutating genes for the preservation of genomic integrity, and expedite the process by directly generating numerous additional mutational events. Genomic instability and ensuing tumor progression thus become the combined result of endogenous (genetic) and exogenous factors.

Genome instability in cancer is seen in multiple forms. Roughly 10% of adult-onset solid tumors exhibit abundant single or oligobase events seen as microsatellite instability. As discussed below, this arises from defects in DNA mismatch repair during DNA replication. Since repeat sequences are inherently more likely to generate small replication errors because of slipped mispairing during replication, the phenomenon is most readily seen in repetitive microsatellite sequences. A small number of genes such as *TGFβ-RII* contain coding repeat sequences, and in tumors arising by microsatellite instability, mutations in such genes become selected for. These tumors have very few other mutations within nonrepeat coding sequences.

Genome instability in cancer is more often seen on a larger scale, in the form of chromosomal instability or aneuploidy. Entire chromosomes are missing or present in extra copies, arising from inappropriate chromosomal segregation during mitosis generating aneuploidy. Translocations generating recombinant and/or truncated chromosomes additionally occur, and multiple recombination events can arise within a single chromosome. Spectral karyotypic analysis of multiple cells from a single tumor reveals differences between cells, as chromosomal instability continues during tumor growth and genomic heterogeneity develops (Fig. 1).

Intrachromosomal instability adds a third fundamental element to the genomic complexity of solid tumors, in the form of numerous insertions, deletions, inversions, amplifications, and other smaller events. The estimated number of such events is increasing as our ability to detect and resolve them improves, with current rough estimates of around ten thousand events per tumor cell. The failure to detect genomic damage in the forms of microsatellite instability or chromosomal instability should not be taken to mean there is no genomic instability at all in a tumor.

Inherent advantages exist for aneuploidy to cooperate with intrachromosomal instability during tumor progression. In order to remove both alleles of a key regulatory gene through aneuploidy alone, both copies of the chromosome will have to be lost. But along with the gene of interest, other genes essential for cellular viability inevitably become lost, bringing the somatic evolutionary process of tumor progression to an abrupt end. On the other hand, mechanisms, which alone generate small events, also have problems; the probability of hitting both alleles of a given gene become very low as the event size shrinks. But when a process generating small events cooperates with a process generating chromosomal instability, critical genes can readily be mutated and the normal allele lost, still without killing the cell (Fig. 2). The evolutionary process of tumor progression is then free to slowly unfold.

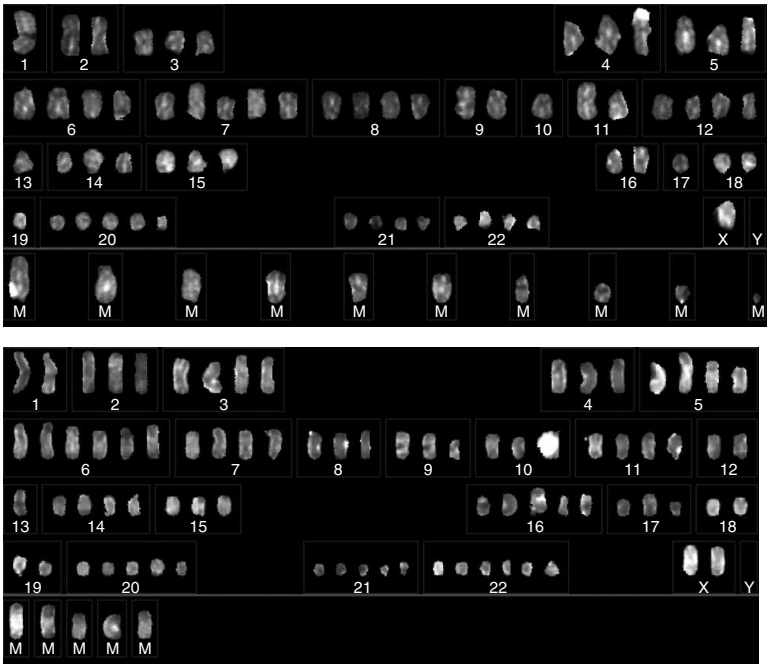

Fig. 1 Genomic instability gives rise to genomic heterogeneity within each tumor. Two cells from the same tumor, colon 5, differ extensively at the genomic level when analyzed by spectral karyotyping. Chromosomes designated M represent a variety of different translocations. Image is from Bartos et al. (2004).

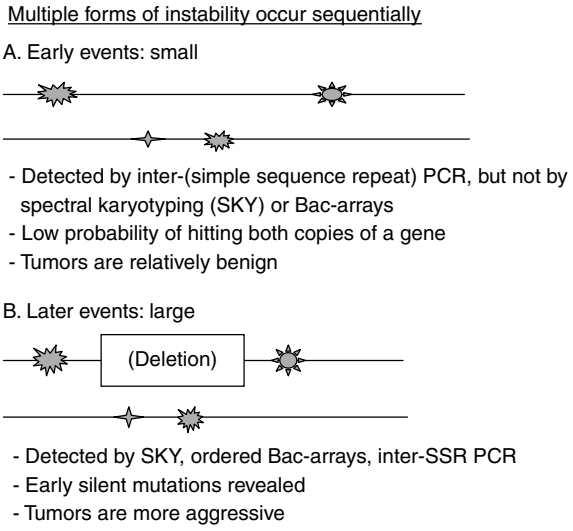

Fig. 2 Multiple forms of genomic instability arise during tumor progression. Inherent advantages exist for small-event instability to cooperate with large-event instability.

This article focuses on genomic instability at the genetic level, where cells acquire permanent heritable changes. An additional level of genomic instability occurs at the epigenetic level, where changes in DNA methylation patterns, particularly of CpG islands, can block the expression of otherwise normal genes. Clinically, this is a significant source of microsatellite instability, when the mismatch repair gene *MLH1* is silenced epigenetically. Complicating the study of epigenetic events in cancer is the finding by Smiraglia and colleagues that DNA methylation patterns of cell lines grown in culture exhibit major differences from the patterns of tumors themselves, presumably reflecting the silencing of genes superfluous to the artificial culture environment.

2
When Does Genomic Instability Begin?

2.1
Onset Early in Tumor Progression

Lawrence Loeb was first to clearly point out the need for genomic destabilization to permit the several requisite steps to convert a normal cell into a malignant tumor cell. This became more evident upon the seminal demonstration by Land et al. that mutation of two cooperating oncogenes alone was insufficient to produce malignancy in mice, and the observations by White, Vogelstein, and others that several events in addition to suppressor gene loss occurred during human colorectal tumor progression. On the basis of known normal mutation rates and the need for more than two mutational events, somatic evolution to malignancy had to somehow be facilitated by decreasing genomic stability.

However, that viewpoint is still not universally accepted. Rubin, Duesberg, and others postulated that normal mutation rates applied to a large, rapidly proliferating cell population, such as the stem cells in colonic crypts, would be likely to generate a rare cell, with exceptional bad luck, containing all the necessary mutations to produce malignancy. This cell would then expand its population inexorably, generating the malignant tumor. By this reasoning, tumors should be essentially homogeneous at the genomic level, but recent spectral karyotyping analyses of multiple tumor cells clearly show this not to be the case.

Verification of the Loeb model has come from multiple directions, centering on demonstration of extensive genomic damage within tumor cells, the finding of extensive genomic heterogeneity within tumors, and tissue culture assays of genomic instability using tumor cell lines showing substantially elevated gene amplification rates. Since genomic instability describes an ongoing process, it is important that these separate forms of evidence exist. Extensive genomic damage occurring in a single burst, as can be seen clinically when induced by radiation therapy or chemotherapy, does not establish that instability exists; in contrast, true genomic instability generates progressively accumulating genomic alterations and genomic diversity within a tumor.

Measuring genomic damage is a complex task, reflecting the diversity of forms of damage that may be present. Flow cytometry measurement of DNA content per cell provides a rough measurement of overall aneuploidy, but karyotyping is essential for identification of specific chromosomal gains and losses. The advent of spectral karyotyping has greatly simplified such analyses, and while also revealing

more complex chromosomal translocation events. Comparative genomic hybridization to entire metaphase chromosomes reveals amplifications and deletions of chromosomes and chromosomal fragments, ranging in size down to a few megabases. These may be integrated within other chromosomes, or may be existing freely in the form of double minutes. Substantially higher resolution is now achievable with the development of ordered Bac-arrays, in which chromosomal regions as small as 150 kb may be analyzed. Finer analyses down to single base size may be achieved through genomic sampling, in which several smaller regions distributed throughout the genome are studied in detail. Arbitrarily primed PCR (polymerase chain reaction) utilizes multiple primers with arbitrary sequences to amplify a small set of broadly distributed products. Inter-(simple sequence repeat) PCR, inter-SSR PCR, utilizes a single primer, anchored within repeat sequences at their 3′ ends facing outward, to amplify those non-repeat sequences between two repetitive elements and generates roughly forty different genomic products per reaction. Both of these techniques provide means of readily sampling the genome to estimate overall damage levels. Direct DNA sequencing of the entire tumor genome is not currently practical, and inevitably becomes complicated by genomic heterogeneity within the tumor cell population. But eventual comparisons of sequence data for individual tumor cell genomes can be expected to yield fascinating data.

Examination of premalignant colorectal adenomas demonstrated that extensive genomic damage begins early in tumor progression. Inter-(simple sequence repeat) PCR analysis shows several thousand genomic events have occurred in early adenomas, a level similar to that seen in frank carcinomas. Such results do not mean that further genomic damage does not accumulate during progression, however. In the inter-SSR PCR analyses, DNA from million cell specimens were used, making later events not present in a majority of cells of the specimen undetectable by this method. Karyotypic analyses of early adenomas, including spectral karyotypes, confirm early extensive genomic damage in the forms of aneuploidy and translocations. Recent work by Pretlow and colleagues, utilizing arbitrarily primed PCR indicates that certain forms of genomic instability begin even prior to the adenoma stage, and can be detected within approximately one-fourth of aberrant crypt foci. These observations are highly important in establishing that genomic instability begins early, putting it in the proper position to facilitate the somatic evolutionary process of tumor progression. Early reports proposing that genomic instability might simply represent one of the numerous phenotypic differences between malignant and normal cells, being a consequence and not a cause of malignancy, are no longer tenable.

2.2 The Leukemia Exception

Acute leukemias, some chronic leukemias, and a few other uncommon childhood/adolescent cancers present exceptions to this model, affecting cell types when they are particularly vulnerable to tumor development. If a normally proliferating cell type in a nonlimiting environment uncontrollably increases its proliferation rate, or loses the ability to differentiate, mature, and ultimately die, the population of this cell type will expand dramatically. To generate these tumors, the number of mutated genes can be as few as two,

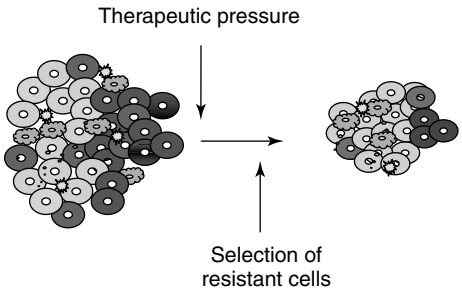

Fig. 3 Extensive genomic heterogeneity within a tumor underlies a considerable part of the eventual failure of pharmacologic therapies for the common, genomically unstable cancers. When therapeutic agents are first applied, susceptible cells are destroyed. But eventually, resistant cells are able to repopulate and further expand the tumor cell population.

which can be generated in a single step by a translocation event that simultaneously rearranges two genes. Such tumors arise rapidly, but due to their genomic homogeneity they also generally respond well to treatment; chronic myelogenous leukemia and its response to Glivec is the classical example of a drug targeted to the translocation event, but childhood acute leukemias also respond well to more conventional therapies. This picture can abruptly change, as such a tumor progresses through blast crisis, giving rise to a genomically unstable heterogeneous tumor cell population capable of evading therapeutic interventions, and in doing so, leukemias can come to resemble the adult-onset solid tumors (Fig. 3).

3
The Maintenance of Genomic Integrity

3.1
DNA Damage Repair

DNA repair is a versatile process evolved to cope with diverse types of DNA damage, which naturally occur. Single base damage elicits base excision repair, while dinucleotide damage (as occurs with UV-induced thymidine dimmers) utilizes nucleotide excision repair. Both of these processes exploit the genetic information present in the undamaged DNA strand. Larger events where breakage occurs can exploit the genetic information present in a sister chromatid or homologous chromosome, through homologous recombinational repair, and still maintain full integrity of the genetic information. While this is feasible in a diploid cell or in a haploid cell in cell cycle phase G2 using the sister chromatid, when allelic losses have occurred or the sister chromatid has not yet been synthesized, the process can fail because of the absence of an intact template. When homologous sequences have been lost or when breakage is extensive, repairs of multiple double-stranded DNA breakage events can still utilize nonhomologous end joining, but with the consequential loss of genomic integrity at the translocated repair sites. Further problems arise if chromosomal fragments are not reintegrated into whole chromosomes; either the genetic information is lost or the small fragment circularizes, with the risk of over-replication and amplification.

In cancer, examples are known for defects in each of these systems, as well as germ-line defects giving rise to hereditary cancer syndromes. The first such case identified was the causal relationship between mismatch repair defects and hereditary nonpolyposis colorectal cancer. Although germ-line defects are found in

the family cancer syndrome, with mutations predominantly in hMLH1 and hMSH2, microsatellite unstable sporadic colon cancers (about 10% of sporadic colon cancers) also exhibit defects in this same system, either arising from somatic mutations or epigenetic silencing. Identification of *BRCA1* and *BRCA2* as the major genes behind familial breast cancer, and the subsequent elucidation of the roles of these genes in homologous recombinational repair, reinforced the concept of defective repair genes underlying both genomic instability and the subsequent cancer arising after decades of somatic evolution.

3.2 High-fidelity DNA Replication

DNA replication is the point where genomic integrity inherently becomes most vulnerable, and most malignancies correspondingly arise out of the relatively rapidly proliferating cell populations such as those lining the gut or in the basal layer of the skin. During replication, the three billion base pairs of the human genome must be copied accurately, completely, and only once, during the few hours that constitute S-phase. This may be occurring in an environment contaminated with carcinogens, reactive oxygen species, or other agents that may damage DNA. And once the DNA is replicated, it must be accurately segregated to daughter cells during mitosis. In spite of these difficulties, and the fact that billions of cells endure these constraints over seven decades, most of us complete our lives never having developed a malignancy.

How is such precision achieved? DNA replication involves over two hundred separate gene products, in a most intricate orchestration. Aside from the highly functional gene products themselves, two keys are the ability to monitor the quality of the replication product, repairing damage immediately, and the ability to temporarily halt replication through checkpoint activation, waiting to resume until the more major damage is repaired. And as a final safeguard, the cellular suicide process of apoptosis is ready to eliminate any cell with irreparable damage to its genomic integrity.

While DNA repair draws most attention as a foundation for genomic instability and tumor progression, uncorrected errors introduced during DNA replication are equally serious and are known to underlie some familial cancers. Mismatched repair errors, in particular, give rise to hereditary nonpolyposis colorectal cancers and endometrial cancers. Errors arising during normal DNA replication are in general within the capability of repair systems to process, but high-level error rates have the potential to exceed normal repair capacities.

3.3 Chromosomal Segregation during Mitosis

The first known form of genomic instability in cancer was aneuploidy, ranging from extra or missing copies of single chromosomes up through tetraploid or higher states, where entire additional copies of the complete genome are present. These phenomena arise out of inaccurate segregation of daughter chromosomes during mitosis. One common diagnostic hallmark of solid tumors is the presence of multipolar mitoses leading to inappropriate segregation.

Centrosomal anomalies typically underlie such inaccurate segregation; these in turn can be a consequence of oncogene activation as shown by Duensing et al. Thus, a stimulus for overproliferation can

promote further tumor progression by giving rise to this particular form of chromosomal instability in turn leading to the loss of suppressor or other growth inhibitory genes, extra copies of growth-promoting genes, and the like. Qualitative changes in these genes, however, do not arise out of aneuploidy; for this reason there is a selective advantage during tumor progression to bring intrachromosomal instability into play. Apparent centrosomal abnormalities can also arise from improper separation of sister chromatids during mitosis, as is seen with separate defects.

3.4 Destabilized Chromosomes: Telomeres

Chromosomal ends are capped with unique structures, telomeres, which are recognized as end structures, and thus are not subjected to ligation-mediated repair. Human telomeres contain eight-base DNA-repeat sequences, totaling around 10 kb in length in young individuals. Telomeres shorten in somatic cells as they undergo repeated rounds of replication as part of the normal maturation process, since the telomerase that generates these cap structures is only active during embryonic development and in germ cell generation.

When telomeres are short or absent, chromosomes become very sticky at their ends as repair is attempted through ligation. This generates a dicentric chromosome, with two centromeres. Alternatively, exonuclease processing may play a significant role in generating dicentric chromosomes. During mitosis, dicentric chromosomes are broken randomly as the daughter cells separate. In turn, these breakpoints are highly unstable, fusing into other chromosomes or generating small circular chromosomal structures. This entire process is known as *bridge-breakage-fusion*, and represents one means of producing translocations and deletions. Amplifications can also arise as circular structures overreplicate and randomly reintegrate.

Telomere deficiency is able to promote tumor development in mice, and human cells with severely shortened telomeres are associated with tumor formation. Since telomerase is reactivated in many tumor cells as part of the acquisition of cellular immortality, telomere-mediated instability is likely to play a larger role relatively early in tumor progression. Attempts at treating cancer by interfering with this reactivated telomerase may be counterproductive as genomic instability is driven higher, although this would relate to the relative rate of increase in genomic instability compared to the relative rate at which the cells then progress to senescence.

3.5 When All Else Fails: Apoptosis. And without it, Trouble

Maintenance of genomic integrity includes the fail-safe mechanism of apoptosis to cause the self-destruction of cells, which in spite of their several DNA damage repair systems and replication checkpoints, still manage to contain significant unrepaired or incompletely repaired damage. Apoptosis utilizes sensors to detect DNA damage; these particularly rely on the ataxia telangiectasia mutated (ATM) protein family to sense broken DNA and trigger a kinase cascade leading through capase activation to cell destruction. Antiapoptotic mechanisms exist to suppress uncalled-for suicide, utilizing in particular the Bcl2 system. Overexpression of Bcl2

can promote hematologic malignancies simply by preventing proper numerical control of specific cell populations.

For solid tumors accumulating extensive DNA damage during their years of progression, defects in the apoptotic pathway are widely seen and play their own crucial role. As genomic damage accumulates, these cells survive and progress further, instead of altruistically eliminating themselves.

4
In the Clinic

4.1
Heterogeneous Tumor Cell Populations and the Therapeutic Target Problem

Medical oncology has achieved notable curative success in the treatment of acute childhood leukemias responding to agents targeting proliferating cells, and excellent if not curative responses have been achieved in a few adult tumors such as chronic myelogenous leukemia, where the etiologic Philadelphia Chromosome translocation provides a specific target in the recombined Abl kinase.

However, medical oncologists have achieved far less success in the treatment of adult-onset solid tumors, where death may be delayed but cure is rarely achieved. The same genome instability necessary for tumor progression to occur has an additional negative consequence as genomic diversity permeates the tumor cell population. Genetic events frequently seen in a tumor type are not present in all cells of the tumor, unless the event occurred very, very early in progression and all tumor cells have descended from a cell with that event. Apc evidently represents such a target for colorectal tumor progression, but even here alternative mutations occurring later in progression may create alternatives to the initiating event. And targeting a totally lost gene, such as with adenovirus cytocidal to p53-negative cells, is proving to be even more difficult than targeting a specific alteration.

This problem can be further illustrated with two antibody-based therapies. Herceptin is used in the treatment of breast cancer, directed against the frequently amplified Her2-neu homolog of the epidermal growth factor receptor, which confers a proliferative advantage. Therapeutic failure occurs after several months, largely as a subpopulation of existing resistant tumor cells become selected for and repopulates the tumor (Fig. 3). Antiangiogenic therapies have had considerable theoretical appeal, in that they are directed against the genomically stable endothelial cells of the tumor vasculature. Experimental studies of mouse models with two peptides (angiostatin and endostatin) were highly successful, but have so far yielded disappointing results in human clinical trials. This has been followed by new approaches using monoclonal antibodies targeted at the major angiogenic factor, vascular endothelial growth factor and its receptor. But even here therapeutic failure occurs within a few months. Heterogeneous tumor cells produce several different angiogenic factors, and the elimination of one system soon selects for cells utilizing other factors.

It now appears reasonable to conclude that therapeutic rehabilitation of adult-onset solid tumor cells is likely to be an exercise in futility. And based on results seen up to the present with even the newest classes of tumor cell targeted agents, the same could relate to therapies, even combination therapies, targeted at specifically killing the tumor cells. For within each such tumor there is a genomically diverse cell population,

exploiting a variety of pathways, and with a broad spectrum of genomic defects in individual cells. Common events will be present in various lineages, akin to the branches of a tree, and various recurring means of effecting proliferation and evading host defenses will be selected, but diversity and heterogeneity will almost always be present to some extent.

So how can cancer ever be cured? We must never forget that currently almost half of all cancers are indeed cured, and those successes are principally the result of surgical resection. If the patient is physically separated from the heterogeneous tumor cell population, the heterogeneity arising out of tumor cell genome instability no longer matters. Surgery, although relatively costly and associated with its own morbidities and mortalities, is the most effective approach to curing cancer, and efforts directed at improving surgical capabilities have genuine potential. Improvements in diagnosis and detection through imaging, molecular diagnostics, and patient-friendly screening approaches, can significantly improve the ability of the surgeon to cure cancer patients. This, combined with proven prevention strategies directed at tobacco and other environmental factors, should not be neglected in favor of glamorous but marginally effective new therapies.

4.2 Genomic Instability as a Clinical Prognostic Tool

Clinical application of genomic instability for purposes of diagnosis and prognosis is constrained by the limitations of assaying a biopsy specimen *in vitro*, and generally at a single point in time. Thus, what is being measured is more accurately genomic damage, but even from this, meaningful clues often can be obtained. Tumors with more extensive damage typically will reflect more rapidly evolving populations, when comparisons are made on a stage-for-stage basis and patients with prior DNA damaging therapies are excluded. Multiple biopsies can reveal genomic heterogeneity within the tumor cell population, which in turn further reflect the likelihood that cells resistant to any given therapy are already present.

The form of genomic instability present also has major clinical implications, in terms of genomic diversity. Microsatellite instability generates approximately 600 000 events, but since few genes contain coding repetitive sequences, relatively little damage to genetic information occurs. And such tumors generally have a good prognosis. With hematologic malignancies, acute childhood diseases driven by a single translocation provide a homogeneous target, and also respond to therapy. But once aneuploidy and intrachromosomal damage becomes extensive, as in blast crisis, therapeutic outcome becomes poor.

The selection of a clinically practicable assay methodology is not a trivial matter. A few approaches have demonstrated their practicability for providing genome-wide information in a clinical setting. Spectral karyotyping, in which chromosomes are painted with specific probes, requires short-term cell culture but reveals considerable information in terms of aneuploidy and chromosomal rearrangements. The cost and expertise level required for this technique presently make it of rather limited general clinical utility.

Array-based approaches comparing tumor DNA with normal DNA effectively reveal amplifications and deletions, in a higher resolution form of comparative genomic hybridization. Such approaches can exploit conventional expression arrays, but with nuclear DNA copies substituting for

cDNAs copied from mRNA. Alternatively, specialized arrays utilizing ordered bacterial artificial chromosomes (Bacs) can representatively scan the entire genome, at a resolving power of about 150 kb. Future improvements in resolution, exploiting single nucleotide polymorphisms, can be anticipated. Current analyses of array data are not yet practical for widespread clinical application due to cost and limitations in data evaluation, although this should be surmounted in the near future.

An alternative approach is the application of genomic sampling methodologies, arbitrarily primed PCR and its variant, inter-(simple sequence repeat) PCR. In these approaches, small pieces of the genome are amplified by PCR, and these genomic samples prepared from tumor DNA are compared with genomic samples prepared from the patient's normal tissue DNA. An electrophoretic comparison of the PCR products reveals what fractions of the bands are altered, providing a quantitative estimate of the degree of genomic damage.

These methodologies have been applied as a prognostic tool for breast cancer, ulcerative colitis, and colorectal cancer, along with Barrett's esophagus. Genomic instability quantitated by inter- (simple sequence repeat) PCR has further been shown to be capable of distinguishing between thyroid tumors and benign lesions, which should be of substantial utility in dealing with relatively common thyroid nodules of indeterminate cytology, which heretofore have been surgically removed as a precautionary measure.

5 A Difficult Future

Genomic destabilization is inherent in the process of development of the common adult-onset cancers. This same instability gives rise to genomic and cellular heterogeneity within the tumor as it presents in the patient; such heterogeneity generates serious problems for nonsurgical therapeutic approaches.

Yet, all is not hopeless. Most cancer cures are currently achieved with surgery, and there remains considerable room for improvement in this area. Promising routes for the future include improving early detection, particularly through the use of proteomic technologies, in turn enabling more timely surgical intervention before metastasis has occurred. Identification of at-risk individuals with familial cancer genes, and definition of tumor specific markers and tests, both fall in the area of early detection. Targeting the genomically stable endothelial cells of the tumor vasculature has its own inherent advantages over targeting the genomically unstable and genomically heterogeneous tumor cell population. And basic prevention measures such as eliminating tobacco use must not be taken lightly.

The cancer problem will be solved neither quickly nor easily. But as the nature of the disease becomes better appreciated, research efforts will hopefully come to focus more on truly productive areas.

Keywords

Atomic Force Microscopy
Atomic force microscopy (AFM) is the key analytical tool in nanobiotechnology. Initially developed for materials science, AFM is nowadays routinely applied to study biomolecular conformation and also reactivity.

Biotemplating
Utilization of the topographic and electrostatic properties of biological macromolecules as a template to grow inorganic structures by deposition of metals and metal ions. Examples of biomolecular templates include grids and hollow cages formed by protein-building blocks and nucleic acid–based architecture.

Directed Assembly
Organization of components mediated by molecular recognition systems. In Nanobiotechnology, often protein and DNA fragments are used to either direct the assembly of nanoparticles in homogeneous solution or to mediate the immobilization of the particles on a solid substrate.

Nanoparticles
Nanometer-scaled particles from metal or semiconductor materials. The latter are often referred to as ''quantum dots'' (QDs). Nanoparticles reveal strongly size-dependent properties, such as the wavelength of light emission from luminescent QDs.

Supramolecular Structure
An aggregate comprised of various molecular or colloidal components held together by noncovalent interactions, such as hydrogen bonding, Van-der-Waals or Coulomb forces.

Nanobiotechnology is a novel field of science, currently emerging at the intersection of materials research, nanosciences, and molecular biotechnology. This highly interdisciplinary field is closely associated to both the physical and chemical properties of organic and inorganic nanoparticles, as well as to the various aspects of molecular cloning, recombinant DNA and protein technology, and immunology. Evolutionary optimized biomolecules, such as nucleic acids, proteins, and supramolecular complexes thereof, are utilized in the fabrication of nanostructured and mesoscopic architecture from organic and inorganic nanoparticles and vice

versa; technical nanometer-scaled devices are used to exploit structure and reactivity of biological systems. This chapter, in particular, is focused on a key issue of nanobiotechnology, concerning the utilization of biomolecules to functionalize inorganic nanoparticles.

1 Concepts

1.1 General Concept

''Nanobiotechnology'' is a novel field of research at the crossroads of biotechnology and nanosciences. Each of these two disciplines themselves are cross sections from various research fields, including fundamental sciences such as physics, chemistry, and biology, as well as engineering and computational sciences. Although nanobiotechnology has often been considered as one of the key technologies for the twenty-first century, its contents and applications are still very much in the process of definition and configuration. Despite the early stage of development, an increasing number of contributions from very diverse directions is claiming the label ''nanobiotechnology.'' Driven by the current hype, for example, even the dispension of nanoliter volumes of aqueous solutions containing biomolecules has been considered as a topic of nanobiotechnology. We will use a more stringent definition here: The use of (individual) biomolecules for technical applications involving devices with at least two dimensions in the submicrometer regime, and/or vice versa, the use of technical nanometer-scaled devices to exploit biological structure and reactivity.

1.2 Topics of Nanobiotechnology

Natural evolution has led to incredibly functional assemblages of proteins, nucleic acids, and other macromolecules to perform complicated tasks that are still daunting for us to try to emulate. As an example, the 20-nm ribosome particle is a most effective supramolecular nanomachine, which spontaneously self-assembles from its more than 50 individual protein and nucleic acid building blocks, thereby impressively demonstrating the power of biologically programmed molecular recognition. Starting with the discovery of the DNA double helix structure, biology has meanwhile grown from a purely descriptive and phenomenological discipline to a molecular science. In view of the revolutionary developments in molecular biosciences, it seems particularly challenging to fuse biotechnology with materials science. The combination of these two disciplines will allow us to take advantage of the evolutionary improved biological components for generating new smart materials, and vice versa, to apply today's advanced materials and physicochemical techniques to solve biological problems. A first systematic and comprehensive survey on this novel interdisciplinary field has recently been published, covering contributions from bioorganic and bioinorganic chemistry, molecular biology, materials science, bioanalytics, and microsystems technology (Table 1).

Owing to the broad-range topics rapidly being developed in the area of nanobiotechnology, it is impossible to cover the entire field, and thus this chapter rather is focused on a key issue of nanobiotechnology, concerning the utilization of biomolecules to functionalize inorganic nanoparticles. The research of hybrid components comprised of biomolecules and inorganic nanoparticles is currently attracting much attention because of the broad spectrum of applications ranging from life sciences to materials and nanosciences.

1.3 Inorganic Nanoparticles Meet Biomolecules

The motivation is based on the unique properties of the two classes of building blocks. Inorganic nanoparticles possess strongly size-dependent optical, electrical, magnetical, and electrochemical properties, while biomolecules, such as proteins and nucleic acids, reveal perfect binding properties and biochemical functionality, optimized within billions of years of evolution. Since they are more readily available by synthetic chemical means and are more conveniently to handle than proteins, nucleic acids have, in the early stages, preferentially been used for the functionalization of nanoparticles to provide highly specific binding sites. Proteins have been employed as well to extend the binding capabilities of inorganic nanoparticles; however, instead of to simply utilize their binding properties, a particular challenge of nanobiotechnology concerns the combination of the intrinsic functionality of many proteins, for instance, optic, catalytic, mechanic or switching capabilities, with the distinguished properties of nanoparticles.

Inorganic nanoparticles are particularly attractive building blocks for the generation of larger superstructures. Nanoparticles can be readily prepared from various materials in large quantities by relatively simple methods, and their dimensions can be controlled from one to about several hundred nanometers,

with a fairly narrow size distribution. Most often, the particles are comprised of metals, metal oxides, and semiconductor materials, such as Ag_2S, CdS, CdSe, CdTe, and TiO_2. Semiconductor nanoparticles are often referred to as ''*quantum dots*'' (QDs). The nanoparticles have highly interesting optical, electronic, and catalytic properties, which are very different from those of the corresponding bulk materials and which often depend strongly on the particle's size in a highly predictable way. Examples include the wavelength of light emission from semiconductor nanocrystals, which can be utilized for biolabeling or lasers as well as for the external magnetic field required to switch a magnetized particle, which is highly relevant in magnetotactic bacteria and hard disk drives. Moreover, nanoparticles are obtainable as highly perfect nanocrystals, useful as building blocks for the assembly of larger two- and three-dimensional superstructures. Such assemblies have a huge potential as transducers in biosensing as well as in materials and nanosciences.

Both biomolecules and nanoparticles meet at the same length scale (Fig. 1). Biomolecular components have typical size dimensions in the range of about 5 to 200 nm. Owing to their intrinsic functionality, they are potent building blocks with an appropriate size to bridge the gap between the submicrometer dimensions reachable by classical top–down engineering, for example, photolithography and microcontact printing, and the dimensions addressable by conventional bottom-up approaches, such as chemical synthesis and supramolecular self-assembly.

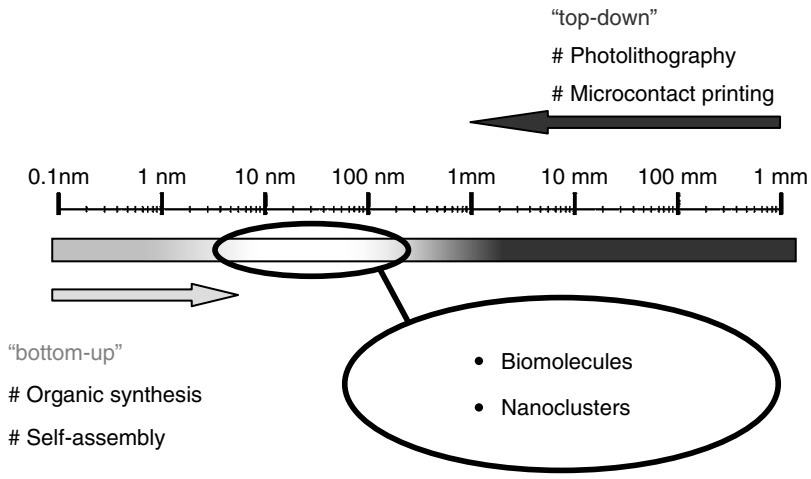

Fig. 1 A gap currently exists in the engineering of small-scale devices. While conventional ''top–down'' processes hardly allow to fabricate structures smaller than about 200 to 100 nm, the limits of ''bottom-up'' processes are in the range of about 2 to 5 nm. Owing to their own dimensions, biomolecules, such as proteins and nucleic acids, and inorganic nanoparticles comprised of metal and semiconductor materials, appear to be suited for addressing that gap. Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128–4158.

2
Protein-functionalized Nanoparticles

2.1
Protein-directed Organization of Particles

Two- and three-dimensional arrays of metal and semiconductor nanoparticles can be fabricated by means of biomolecular recognition moieties (Fig. 2). Initially, two sets of nanoparticles to be organized are functionalized with individual recognition groups, which are either directly complementary to each other, or are complementary to a molecular linker

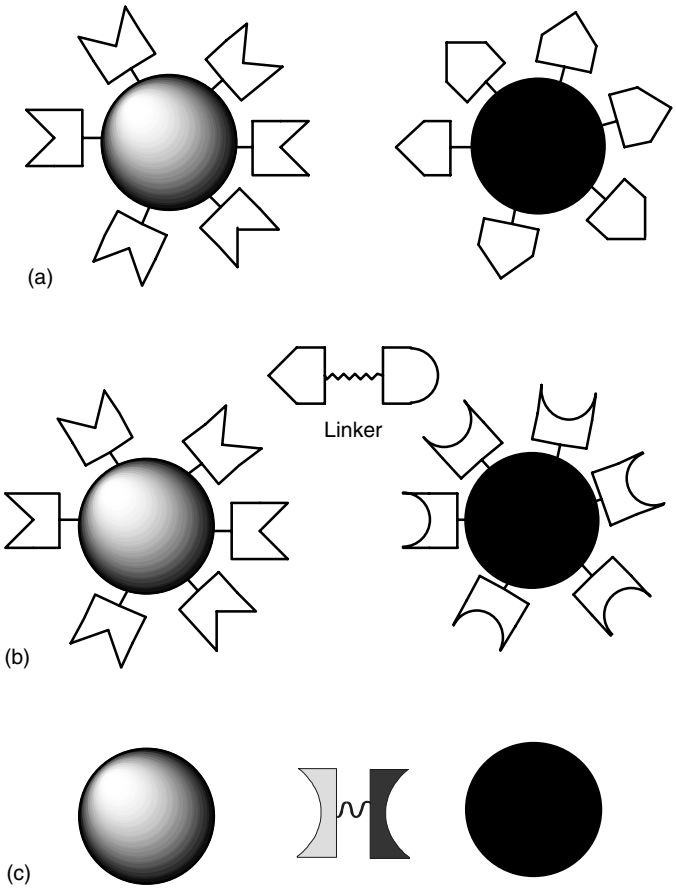

Fig. 2 Schematic drawing of general concepts for solution–phase coupling using biomolecular recognition elements. (a) Two sets of nanoparticles are functionalized with an individual recognition group, which are complementary to each other. (b) The particle-bound recognition groups are not complementary to each other, but can be bridged through a bispecific linker molecule. (c) A bivalent linker, which directly recognizes the surfaces of the nanoparticles is used for oligomerization. Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128–4158.

(Fig. 2a and b respectively). Driven by the biospecific interaction, the two particle batches assemble to extended nanoparticle networks, which, in some cases, can grow to the size of macroscopic materials. The major motivation for this approach is based on the unique properties of biomolecular linkers, which promise new applications, such as tunable and switchable materials. In particular, the tremendous recognition capabilities of biomolecules, and their potential to be addressed and manipulated through biochemical procedures using designed tools, such as enzymes, should provide the basis for entirely novel routes to rationally construct advanced materials.

According to the generalized scheme depicted in (Fig. 2b), one example took advantage of the specific interaction between antibodies and low molecular weight organic compounds (haptens). The hapten groups were used to cross-link gold and silver nanoparticles, previously coated with antibody molecules which specifically recognized either the D-biotin or the dinitrophenyl (DNP) group. To allow for the cross-linking of the IgG-functionalized nanoparticles, bivalent linkers were used, which contained two hapten groups in terminal positions. Either the monospecific or bispecific linkers were used, allowing for the directed assembly of homo-oligomeric or heterodimeric aggregates respectively. However, the degree of organization was not as high as expected, indicating that further approaches will require more sophisticated engineering of the antibody–antigen interface. Another example of employing protein-based recognition to organize inorganic nanoparticles was based on the unique interaction between the biotin-binding protein streptavidin (STV) with its low molecular weight ligand D-biotin. The STV-biotin interaction was used to organize gold colloids functionalized by chemisorptive coupling of a disulfide-bridged bis-biotin compound. The particle cross-linking was achieved by the addition of STV as a linker. This process was monitored by spectroscopy and dynamic light scattering (DLS), allowing to determine that the average hydrodynamic radius of all particles in solution rapidly increased upon STV-directed assembly. transmission electron microscopy (TEM) images revealed networks containing on average about 20 interconnected particles, which are separated by about 5 nm, correlating with the diameter of an STV molecule. Recently, an artificial peptide-based linker system was designed to guide supramolecular organization of gold nanoparticles.

2.2 Genetic Approaches to Particle Organization

The power of directed evolution methodology was recently applied to *de novo* generate protein linker units, which directly recognize distinct surfaces of semiconductor materials, thereby avoiding the necessity of previous chemical functionalization (Fig. 2c). Phage-display was used to select 12-mer peptides with binding specificity for distinct semiconductor surfaces. On the basis of a combinatorial library of random 12-mer peptides, comprised of about 10^9 different peptides, phage clones were selected for their specific binding capabilities to five different single-crystal semiconductors, GaAs(100), GaAs(111)A, GaAs(111)B, InP(100), and Si(100). Specific peptide binding was found that is selective for the crystal composition (for example, binding to GaAs, but not to

Si) and crystal face (for example, binding to GaAs(100), but not to GaAs(111). A particular clone was even capable of differentiating between two zinc-blende crystal structures, GaAs and AlAs, which have almost identical lattice constants of 5.66 Å and 5.65 Å respectively. The basis for this selectivity, whether it is chemical, structural, or electronic, is still under investigation. Sequence analysis of various clones has revealed a significantly enhanced portion of amino acids with side chains carrying a Lewis base or Lewis acid group, suggesting that these are important for specific recognition of the substrate. The peptides evolved may be applied to the generation of bispecific linker molecules with binding capabilities for two different semiconductor or metal surfaces (Fig. 2c), thereby paving the way to novel bottom-up approaches for fabricating complex nanoparticle heterostructures.

The genetic selection approach was also used to fabricate highly ordered composite materials from genetically engineered M13 bacteriophage and ZnS nanocrystals. The bacteriophage were coupled with ZnS solution precursors and spontaneously evolved a self-supporting hybrid film material that was ordered at the nanoscale and at the micrometer scale into approximately 70-μm domains, which were continuous over a centimeter length scale. Directed evolution of bacterial surface proteins has been employed to generate proteins with specific recognition properties for gold nanoparticles. Besides opening up novel ways for generating unconventional materials, this work also has implications on the understanding of the fundamental processes of biomineralization, in which protein components control the formation of materials by specifically interacting with growing crystallites.

2.3 Nanoparticle-protein Conjugates as Biolabels

Gold nanoparticles, functionalized with proteins have long been used as tools in biosciences. For instance, antibody molecules adsorbed to 10–40-nm colloidal gold are routinely used in histology, allowing for the biospecific labeling of distinguished regions of tissue samples and subsequent TEM analysis. More advanced, small gold clusters of 0.8 or 1.4 nm diameter can be used for the site-specific labeling of biological macromolecules. These labels have a number of advantages over colloidal probes, including better resolution, stability, and uniformity. Moreover, their small size improves the penetration and more quantitative labeling of antigenic sites. The 1.4-nm particles are the smallest size of gold clusters, which can be seen directly in the conventional electron microscope, allowing for a spatial resolution of about 7 nm when covalently attached to antibody fragments. The clusters visibility can be improved by a wet-chemical silver enhancement step for use in electron or light microscopy for histological purposes, or to detect less than picogram amounts of antigens in immunoblots. The silver enhancement can also applied for the electrical sensing of biological binding events, for instance, via the short-circuiting of microelectrodes (Fig. 3). Gold nanoparticles are immobilized in the gaps of microelectrodes via biospecific interaction such as immunosorption of antibodies. The colloids serve as catalytic cores for the reductive deposition of a conducting layer of silver, which short circuits the two electrodes. The resulting decrease in ohmic resistance is used as a positive signal for the sensing of the biospecific interaction to be detected.

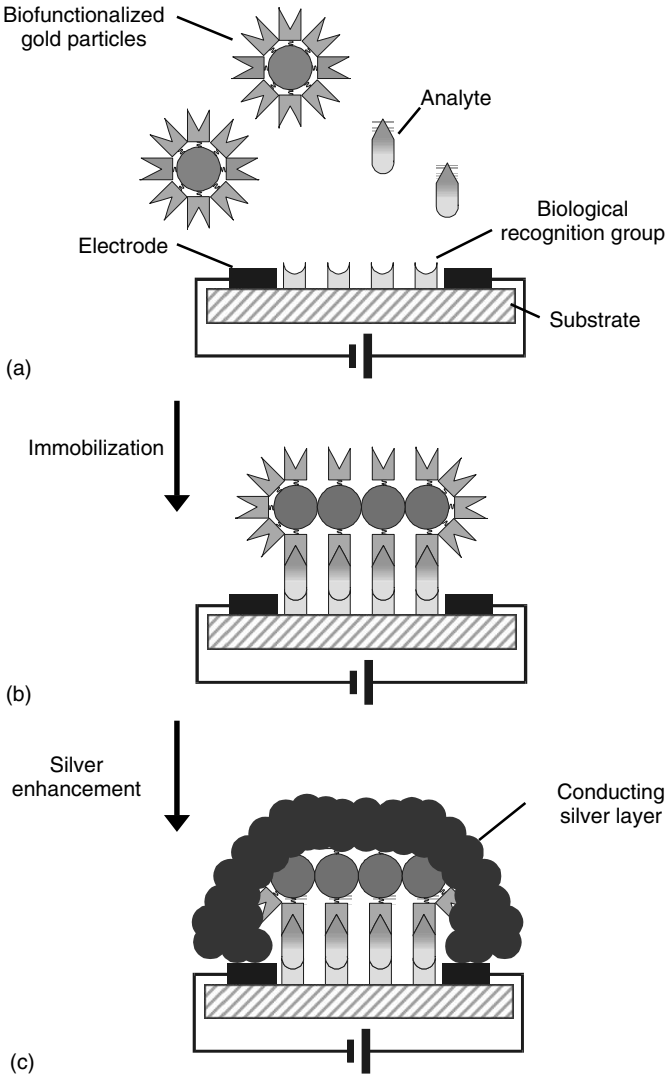

Fig. 3 Electrical sensing of biorecognition events. Receptor groups, such as antibodies or DNA oligomers, immobilized in the gap between two microelectrodes, are used as a capture agent to specifically bind complementary target molecules. In a sandwich-type assay, the captured analyte is tagged with colloidal gold through a second biological recognition unit. Subsequent reductive deposition of silver leads to the formation of a conducting metal layer, which shortcuts the two electrodes. Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128–4158.

Gold nanoparticles can also be applied to enhance detection limits in surface plasmon resonance (SPR)-based real-time biospecific interaction analysis. The dramatic enhancement of SPR biosensing using colloidal gold was initially observed in a sandwich immunoassay in which gold nanoparticles were coupled to a secondary antibody. The latter was used to detect a primary antibody bound through specific immunosorption to the antigen immobilized on the gold sensor surface. The immunosorptive binding of the colloidal gold to the sensor surface led to a large shift in plasmon angle, a broadened plasmon resonance, and an increase in minimum reflectance, thereby allowing for picomolar detection of the antigen. Similarly, an about 1000-fold improvement in sensitivity was obtained in nucleic acid hybridization analysis, using a colloidal gold/oligonucleotide conjugate as a probe.

Semiconductor nanoparticles, often referred to as quantum dots (QDs) are powerful fluorescent probes, which can be used for the labeling of biological components. The QDs have several advantages over conventional fluorescent dyes. Their fluorescence absorption and emission is conveniently tunable by their size and material composition, and the emission peaks have a narrow spectral linewidth (Fig. 4). Typically, emission widths are 20–30 nm (full-width at half-maximum, FWHM), which is only one-third of the emission linewidth of a conventional organic dye. The high quantum yields often range from 35 to 50% for CdSe/ZnS core/shell nanoparticles. Moreover, QDs are about 100-fold as stable against photobleaching as an organic dye, and they often reveal a long fluorescence lifetime of several hundreds of nanoseconds. This allows for time-delayed fluorescence measurements, which can be used to suppress the autofluorescence of biological matrices. As demonstrated in numerous examples, QDs are versatile tools for biolabeling, such as immunostaining and fluorescence *in situ* hybridization (FISH).

2.4 Nanoparticles Modified with Functional Proteins

In addition to simply utilizing the recognition properties of proteins, a particular challenge of current research concerns the coupling of the intrinsic functionality of many proteins, for instance, optic, catalytic, mechanic, or switching capabilities, with the distinguished properties of nanoparticles. Initial steps toward this end concerned the optical interaction between QDs and chemisorbed bovine serum albumin and maltose-binding protein-fluorescent dye conjugates, enabling for the self-assembly of bioconjugates that function as a specific chemical sensor for saccharides. Other studies concerned the employment of chaperonin proteins as switchable nanocages for the specific encapsulation and the ATP-triggered release of QDs, and the ''nanowiring'' of enzymes with electrodes by specific incorporation of 1.4-nm gold nanoparticles into the active site of glucose oxidase redox enzymes. Moreover, mechanically active hybrids comprised of nanostructured inorganic components, and biomolecules were constructed taking advantage of motor proteins. This was achieved from a recombinant F_1-ATPase, immobilized at 80-nm diameter nickel posts and coupled with a nanopropeller of ca. 1000-nm length. The ATPase molecule, which is capable of producing about 100 pN*nm

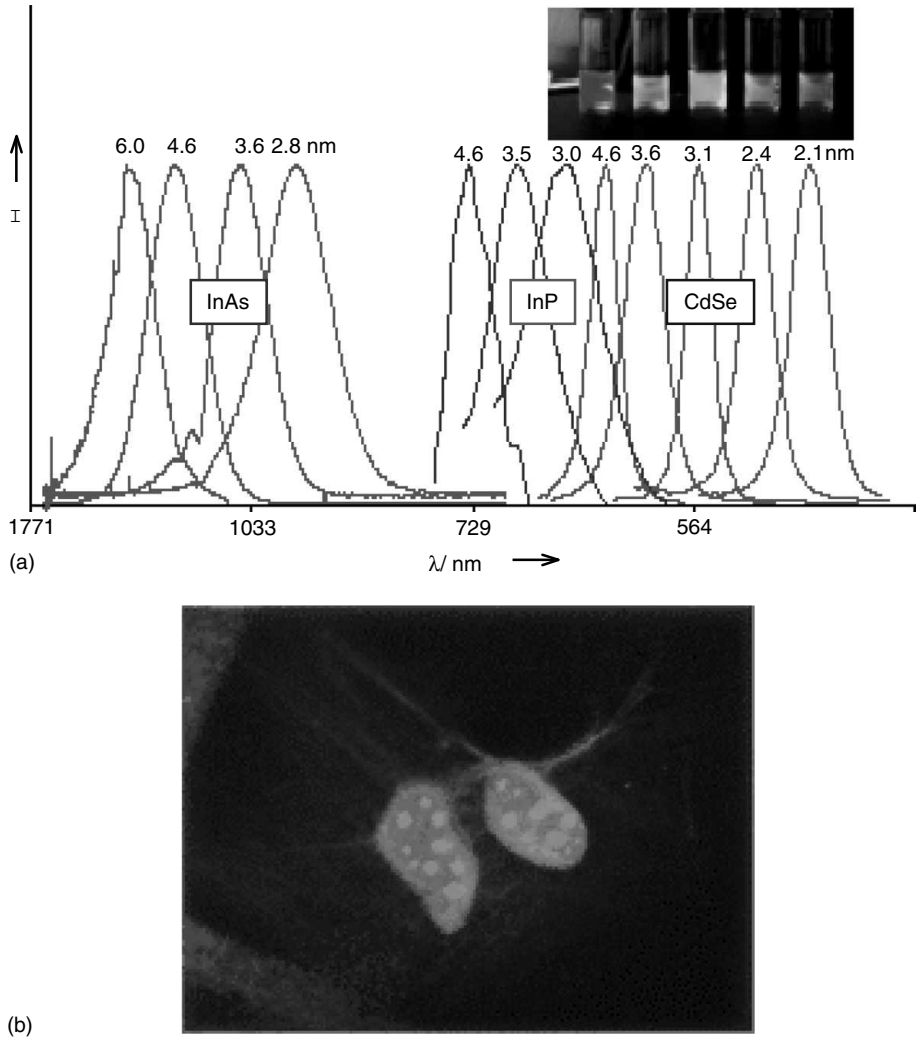

Fig. 4 (a) Fluorescence absorption and emission spectra of semiconductor quantum dots; (b) Cross section of dual-labeled mouse fibroblasts. The actin fibers are stained red. The nonspecific labeling of the nuclear membrane by both the red and the green probes results in a yellow color. Reprinted with permission from Bruchez, Jr., M., Moronne, M., Gin, P., Weiss, S., Alivisatos, A.P. (1998) Semiconductor nanocrystals as fluorescent biological labels, *Science* **281**, 2013–2015.

of rotary torque by hydrolysis of ATP, rotates the propeller with a velocity of about 5 rounds/s. These reports illustrate how biological systems can be tuned by nanostructured inorganic components and vice versa, how the properties of inorganic particles can be extended by biomolecular mechanisms, and thus these studies have added new facets to nanobiotechnology.

3
DNA-based Nanoparticle Assemblies

DNA is a particularly powerful construction material in nanosciences. The enormous specificity of Watson–Crick base pairing allows the convenient programming of artificial DNA receptor moieties. The power of DNA as a molecular tool is enhanced by our ability to synthesize virtually any DNA sequence by automated methods, and to amplify any DNA sequence from microscopic to macroscopic quantities by PCR. Another very attractive feature of DNA is the great mechanical rigidity of short double helices, so that they behave effectively like a rigid rod spacer between two tethered functional molecular components on both ends. Moreover, DNA displays a relatively high physicochemical stability, and nature provides us with a variety of highly specific enzymes, which allow for processing of the DNA material with atomic precision and accuracy on the angstrom level. No other (polymeric) material offers these advantages, which are ideal for molecular constructions in the range from about 5 nm up to the micrometer scale. Consequently, DNA has already extensively been used for constructions on the nanometer length scale, and recent advances indicate its applicability for fabricating nanomechanical devices. The following sections will focus on the use of DNA as a construction material for the fabrication of nanoparticular assemblies.

3.1
DNA-directed Oligomerization of Nanoparticles

Following the generalized scheme in (Fig. 2b), DNA hybridization has been used to generate repetitive nanocluster materials (Fig. 5). Two noncomplementary oligonucleotides were coupled in separate reactions with 13-nm gold particles via thiol adsorption. A DNA duplex molecule containing a double-stranded region and two cohesive single-stranded ends, which are complementary to the particle-bound DNA, was used as a linker. The addition of the linker to a mixture of the two oligonucleotide-modified nanoparticles led to the aggregation and slow precipitation of a macroscopic DNA-colloid material. This process is reversible. Since the nanoparticles contained multiple DNA molecules, the oligomerized aggregates were three-dimensionally linked, as judged from the TEM analysis. Images of two-dimensional, single-layer aggregates reveal close-packed assemblies of the colloids with uniform particle separations of about 6 nm, corresponding to the length of the DNA linker duplex. This self-assembly can also be used for the generation of binary networks. Owing to the specificity of Watson–Crick basepairing, only heterodimeric ''A-B'' composites with alternating particle sizes are formed (Fig. 5). For example, two types of gold clusters of either 40 or 5 nm diameters were assembled by DNA hybridization. In the case of an excess of one particle, satellite-like aggregate structures were generated and characterized by TEM. Similarly, oligonucleotide functionalized CdSe/ZnS QDs and gold nanoparticles were organized to form binary nanoparticle networks. TEM analysis revealed that the hybrid metal/semiconductor assemblies exhibited the A-B-structure expected, and fluorescence and electronic absorption spectroscopy indicated cooperative optical and electronic phenomena within the network

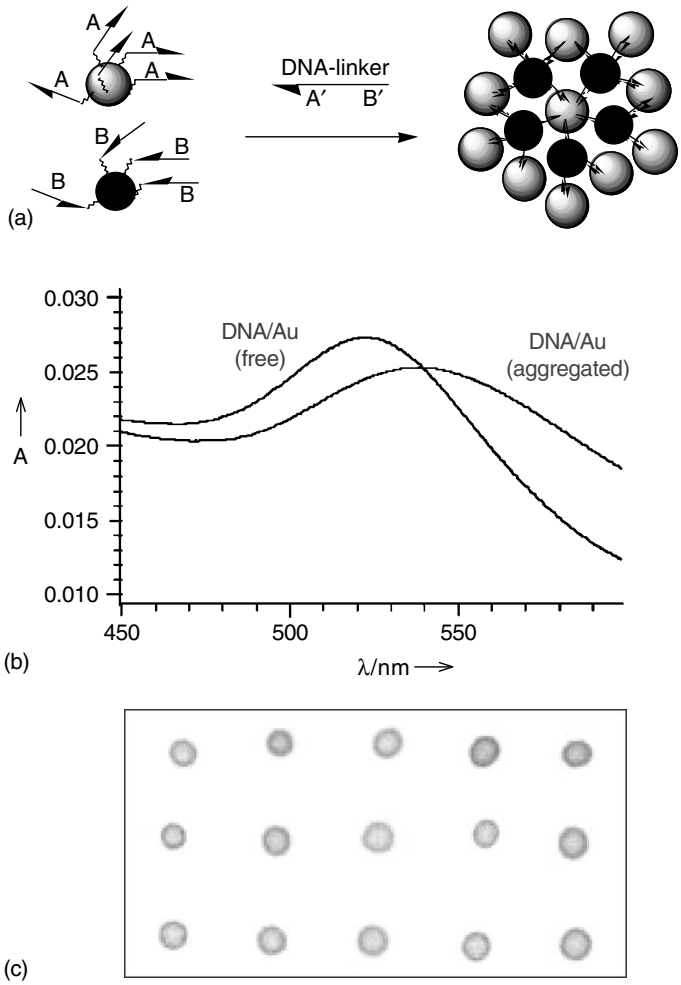

Fig. 5 Assembly of gold colloids using DNA hybridization. (a) Two batches of gold particles, are derivatized with noncomplementary oligonucleotides, either via 5′- or 3′-thiol groups. The nanoparticles are oligomerized using a single-stranded nucleic acid linker molecule. Note that exclusively heterodimeric ''A-B'' linkages are present within network. The network formation leads to a characteristic change in the plasmon absorption (b). The color change can be used to macroscopically detect DNA hybridization using an assay in which DNA/Au conjugates and a sample with potential target DNA is spotted on a hydrophobic membrane (c). Red spots indicate the absence of fully matched DNA, while blue spots are indicative for the presence of complementary target DNA. Data in (c) are reprinted from Storhoff, J.J., Mirkin, C. A. (1999) Programmed Materials Synthesis with DNA. *Chem. Rev.* **99**, 1849–1862. Copyright 1999 American Chemical Society. (See color plate p. xxvi).

materials. Recently, oligofunctional DNA-gold nanoparticle conjugates were developed. These highly functionalized conjugates contained up to seven different DNA oligonucleotide sequences, which were orthogonally addressable and revealed an efficient reactivity comparable to that of the analogous monofunctional conjugates.

Studies of DNA-linked gold nanoparticle assemblies concerned the influence of the DNA spacer length on the optical and electrical, as well as the melting properties of these networks. The experiments provided evidence that the linker length kinetically controls the size of the aggregates, and that the optical properties of the nanoparticle assemblies are governed by aggregate size. In contrast, it was found that the electrical properties of dried nanoparticle aggregates are not influenced by the linker length. Although SAXS clearly indicated the linker length–dependent distances between particles in solution, the networks collapse upon drying, thereby forming bulk materials comprised of nanoparticles covered with an insulating film of DNA. These materials show semiconductor properties not influenced by the linker lengths. The strongly cooperative melting effect of the nanoparticle networks results from two key factors: the presence of multiple DNA linkers between each pair of nanoparticles and a decrease in the melting temperature as DNA strands melt due to a concomitant reduction in local salt concentration. This mechanism, originating from short-range duplex-to-duplex interactions, is independent of DNA base sequences and should be universal for any type of nanostructured probe that is heavily functionalized with oligonucleotides.

3.2 Individual Nanoscaled Particle Assemblies

The oligomeric DNA-nanoparticle hybrid materials (see Sect. 3.1) have promising electronic and optical properties, potentially useful for applications in materials science, and also have a tremendous impact on immediate diagnostic applications, in particular, DNA microarray–based nucleic acid analyses (see Sect. 3.6). To even increase the enormous potential of the DNA–nanoparticle compounds, it is important to overcome limitations, which may result from the lack of stoichiometric control during the assembly process. To control the architecture of nanomaterials, spatially defined arrangements of molecular devices are required. For example, to organize metal and semiconductor nanocrystals into ultrasmall electronic devices, one may consider a linear aggregate of several individual components (Fig. 6). As previously demonstrated for proteins (see Sect 3.3), gold nanoclusters containing a single nucleic acid moiety have been rationally assembled into stoichiometrically defined nanoscale aggregates (Fig. 6b). To this end, well-defined monoadducts were synthesized from commercially available 1.4-nm gold clusters containing a single reactive maleimido group and thiolated 18-mer oligonucleotides. Subsequent to purification, these conjugates allowed the rational construction of well-defined "nanocrystaline molecules" by DNA-directed assembly using a single-stranded template, which contained the complementary sequence stretches (Fig. 6b). Depending on the template, the DNA-nanocluster conjugates were assembled to generate the head-to-head and head-to-tail homodimeric target molecules **1a** and **1b** in approximately 70% purity, as determined by TEM analysis. More recently, multiple gold nanocrystal aggregates were generated by DNA-directed assembly. The preparations, containing up to three nanoclusters of different sizes organized in multiple fashions, were characterized by TEM. The nanocrystal molecules have a high flexibility when the DNA backbone is nicked (e.g. **1c**), while an unnicked double helix (e.g. **1d**) significantly lowers the flexibility. UV/VIS absorbance measurements indicated changes in the

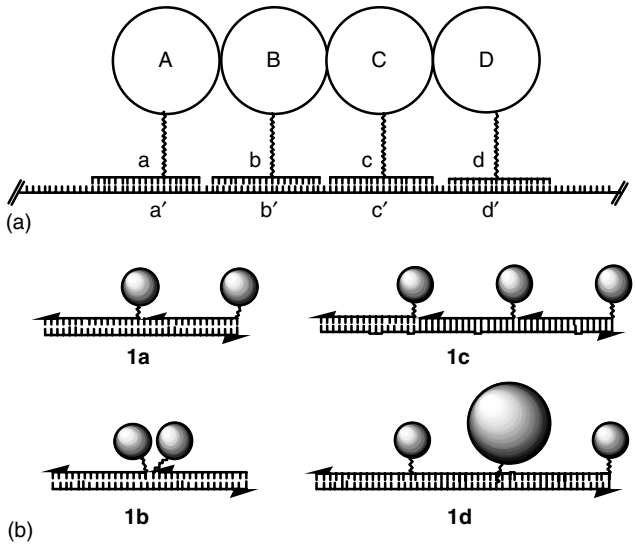

Fig. 6 (a) Schematic representation of DNA-directed assembly of four different nanoscaled building blocks to form a stoichiometrically and spatially defined supramolecular aggregate. (b) Assembly of nanocrystal molecules using DNA hybridization. Conjugates from gold particles (represented as shaded spheres) and 3′- or 5′-thiolated oligonucleotides allowed the fabrication of head-to-head (**1a**) or head-to-tail (**1b**) homodimers. A template containing the complementary sequence in triplicate affects the formation of the trimer **1c**. Aggregate **1d** reveals a limited flexibility owing to the unnicked double helical backbone. Note that, according to the scheme (A), the DNA-directed assembly has been applied to the organization of proteins (see Fig. 7). Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128–4158.

spectral properties of the nanoparticles as a consequence of the supramolecular organization.

3.3
DNA–protein Conjugates as Tools in Nanofabrication

The initial demonstration of using DNA as a framework for the precise spatial arrangement of molecular components was carried out with covalent conjugates of single-stranded DNA oligomers and the streptavidin (STV) protein. Using the STV-DNA conjugates **2** (Fig. 7) as model systems, a variety of essential basic studies on the DNA-directed assembly of macromolecules were carried out, which have been reviewed earlier. The covalent DNA-STV conjugates are also convenient as versatile molecular adapters in the nanofabrication of supramolecular assemblies. The covalently attached oligonucleotide moiety supplements the STV's four native biotin-binding sites with a specific recognition domain for a complementary nucleic acid sequence. This bispecificity

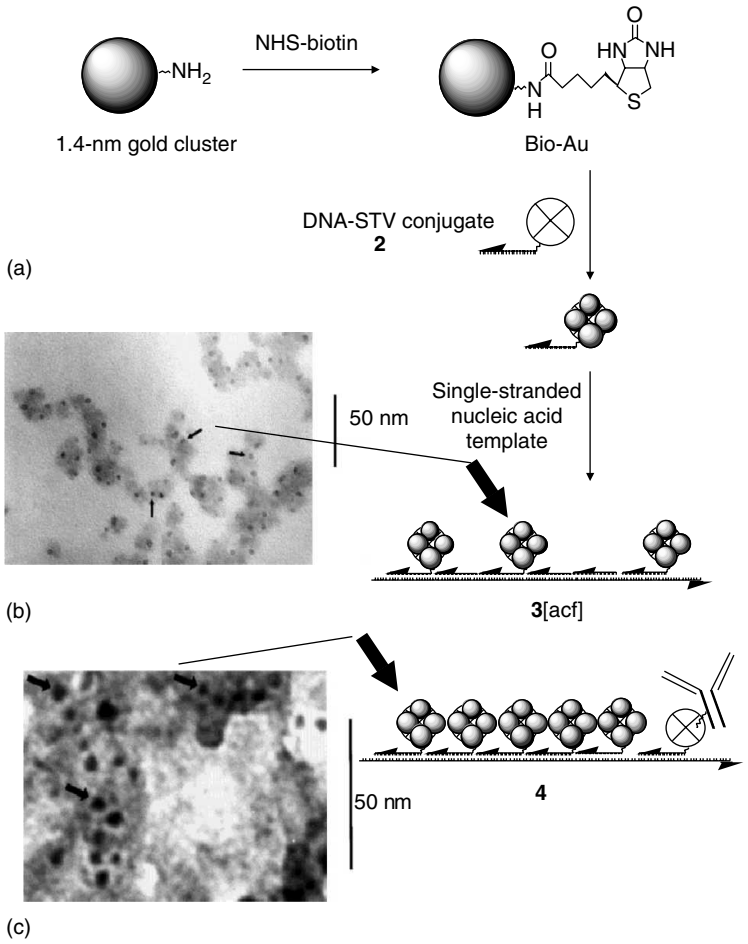

Fig. 7 (a) Schematic representation of DNA-directed assembly of biotinylated gold nanoclusters using covalent DNA-STV conjugates **2** as molecular adapters. The nanocluster-loaded STV conjugates self-assemble in the presence of a single-stranded nucleic acid carrier molecule, containing complementary sequence stretches, to form biometallic aggregates **3**. (b) TEM images of the biometallic aggregate 3[acf] (the letters in brackets indicate for the protein components bound to the template) and an antibody-containing biometallic construct **4** (c). The latter was fabricated from gold-labeled conjugates **2** and a conjugate of **2** and a biotinylated immunoglobulin, previously coupled in separate reactions. Note that the four gold clusters bound to **2** cannot be optically resolved by TEM. Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128–4158.

allows to use the DNA-STV conjugates as adapters to assemble basically any biotinylated compound along a nucleic acid template. For example, the strong biotin–STV interaction and the specific nucleic acid hybridization capabilities of the DNA-STV conjugates **2** were utilized to organize gold nanoclusters (Fig. 7). To this end, 1.4-nm gold clusters containing a single amino-substituent were derivatized with a biotin group, and, subsequently, the biotin moiety was used to organize the nanoclusters into the tetrahedral superstructure, defined by the biotin-binding sites of the STV. Subsequently, the nanocluster-loaded proteins self-assemble in the presence of a complementary single-stranded nucleic acid carrier molecule, thereby generating novel biometallic nanostructures, such as **3** (Fig. 7). Since the DNA-STV conjugates can be used like a molecular construction kit, this approach even allows the combined assembly of inorganic and biological components to fabricate functional biometallic aggregates, such as **4**, containing an IgG molecule (Fig. 7). The antibody can be used for targeting the biometallic nanostructures toward certain tissues or other surfaces. This example demonstrates how protein–ligand interaction and DNA hybridization can be used for the nanoconstruction of novel inorganic/bioorganic hybrid systems, and similar approaches should even allow the fabrication of highly complex supramolecular structures. It should be noted, at this point, that Seeman and coworkers have impressively demonstrated the power of DNA in the rational construction of complex molecular framework. For instance, they synthesized the ''truncated octahedron,'' a DNA polyhedron containing 24 individual oligonucleotide arms at its vertices, which can, in principle, be used as a framework for the selective spatial positioning of 24 different proteins, inorganic nanoclusters, and/or other functional molecular devices.

Even today, very little is known on the manipulation and tailoring of oligomeric nanoparticle networks (see Sect. 3.1), for instance, on ways to influence the structure and topography of the DNA hybrid materials subsequent to their formation by self-assembly. Within the context of basic studies on DNA-linked nanoparticle networks, the oligomeric aggregates **5** (Fig. 8) generated from bioorganic streptavidin (STV) particles and bis-biotinylated dsDNA are suitable model systems to gain insight into the properties of complex particle networks. The STV functions as a 5-nm model particle, which can realize only a limited number of interconnects to other particles within the network. Either one, two, three, or four biotinylated DNA fragments can be conjugated with the STV by means of the high affinity STV–biotin interaction. This simplifies the complexity of the supramolecular particle networks, and thus, allows for the convenient analysis and modeling of effects occurring from variations, for example, in the assembly and immobilization parameters. In addition, the size of the dsDNA linker fragments, which are typically about 30 to 170 nm in lengths, allows for convenient direct observation by (atomic force microscopy) AFM (Fig. 8). These findings are convenient for both disciplines involved: The use of the AFM allows to gain insights into biomolecular structure and assembly dynamics, and, in turn, the well-defined and clearly distinguishable DNA-STV nanostructures can be used as soft-materials calibration standards for the detailed study of tip convolution effects, and the influences of measuring parameters in AFM analyses.

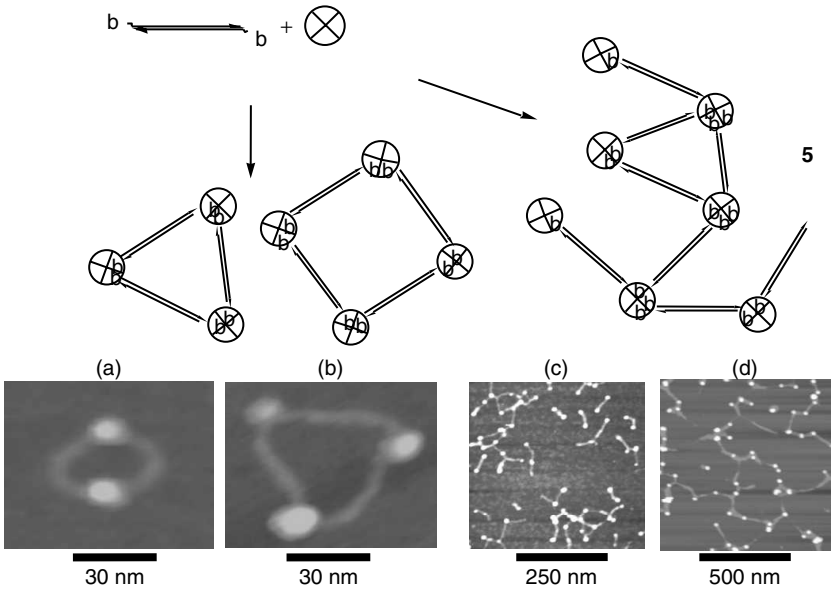

Fig. 8 DNA-protein **5** conjugates as model systems for DNA-interconnected nanoparticles. The synthesis of the networks was achieved by using double-stranded DNA (dsDNA) as spaces. The dsDNA fragments contain two binding sites attached to the two 5′-ends of the double-stranded DNA (b = binding site). The binding sites are either biotinyl groups allowing cross-linking of the biotin-binding protein streptavidin as a model nanoparticle (a-c), or else the binding sites are thiol-groups allowing to connect 5-nm gold colloids (d). The assembly of the two-components not only leads to the formation of oligomeric networks (c, d) but also individual particle aggregates are formed, which can be isolated by electrophoretic or chromatographic methods (a, b). The images at the bottom were obtained by AFM analysis. Reprinted with permission from Niemeyer, C.M. (2001) Nanoparticles, Proteins, and Nucleic Acids: Biotechnology Meets Materials Science, *Angew. Chem. Int. Ed.* **40**, 4128 – 4158.

Mirkin et al. demonstrated that the oligomerization of DNA-coated gold nanoparticles, depicted in Fig. 5, can as well be mediated by conjugates comprised of oligonucleotides and the STV protein. Interestingly, the most thermodynamically stable oligomeric networks are only formed upon heating of the kinetically controlled adducts initially produced. Additional topics of fundamental research on DNA/protein–nanoparticle interaction concern the investigation of whether and how DNA-functionalized particles can be manipulated by DNA-modifying enzymes.

3.4 DNA Biotemplating

The electrostatic and topographic properties of biological macromolecules and supramolecular complexes comprised thereof can be used for the synthesis and assembly of organic and inorganic components. In this ''biological templating'' approach, regular two-dimensional lattices of bacterial cell surface proteins, hollow biomolecular compartments, such as virus particles, as well as nanometer- and micrometer-sized nucleic

acid components have already been exploited for the generation of nanoparticles and supramolecular architecture. Pioneering work on the DNA-templated generation of metal and semiconductor nanoparticle arrays was carried out by Coffer and coworkers. They used the negatively charged phosphate backbone of the DNA double helix to accumulate Cd^{2+} ions, which were subsequently treated with Na_2S to form CdS nanoparticles. The templated growth of palladium clusters was conducted by using λ-DNA, leading to the formation of DNA-associated 1-D and 2-D arrays of well-separated 3- to 5-nm palladium clusters, which were dependent on the initial nucleation of the metal clusters. This was achieved by activating the DNA with palladium acetate and subsequent reduction using a sodium citrate/lactic acid/dimethylamine borane solution. In the DNA-templated fabrication of mesoscale structures from preformed, positively charged 3-nm CdS particles with a thiocholine modified surface, the particles were found to be assembled in a quasi one-dimensional dense packing to form chainlike structures. The electrostatic assembly of lysine-passivated gold particles on DNA or intercalator-modfied gold particles on DNA and polylysine was also reported.

An example of DNA-biotemplating concerned the use of a 16-μm λ-DNA molecule containing two cohesive ends to bridge the about 12- to 16-μm distance between two gold microelectrodes, prepared by standard photolithography (Fig. 9). Subsequent to functionalization of the electrodes with individual capture oligonucleotides,

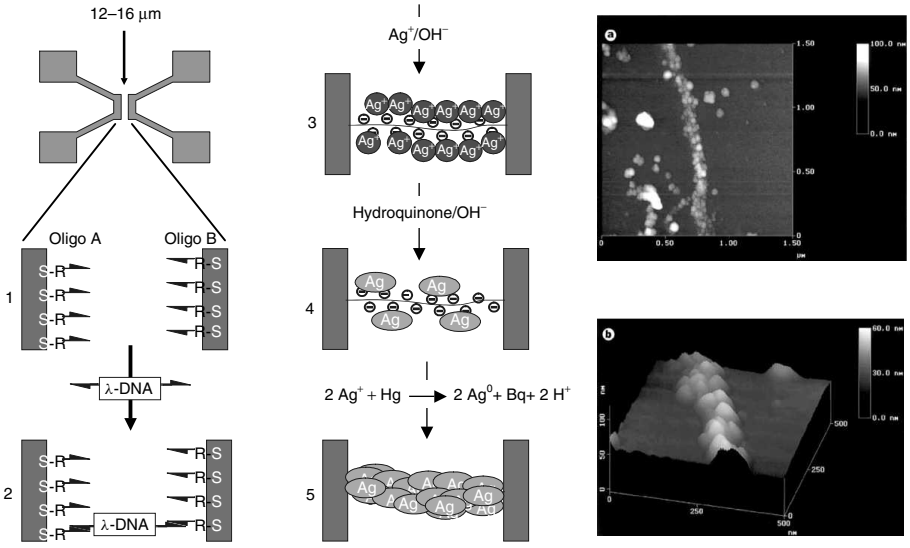

Fig. 9 DNA-templated synthesis of a conductive silver wire. A 16-μm λ-DNA molecule was used to bridge the gap between two gold microelectrodes. The sodium ions bound to the DNA's phosphate backbone were exchanged with Ag^+ ions, and the latter were chemically reduced by hydroquinone to form small silver aggregates. Further reductive deposition of silver led to the formation of a silver nanowire. AFM images revealed the granular structure of the wire. Reprinted with permission from Braun, E., Eichen, Y., Sivan, U., Ben-Yoseph, G. (1998) DNA-templated assembly and electrode attachment of a conducting silver wire, *Nature* **391**, 775–778.

the DNA fragment was allowed to hybridize. Successful interconnection of the electrodes was confirmed by optical microscopy of the fluorescently labeled λ-DNA. Next, the sodium ions bound to the phosphate backbone of the λ-DNA were exchanged with Ag^+ ions, and the latter were chemically reduced by hydroquinone. The small silver aggregates formed along the DNA backbone were then used as catalysts for further reductive deposition of silver, eventually leading to the formation of a silver nanowire. This micrometer-sized element with a typical width of 100 nm had a granular morphology, as determined by AFM (Fig. 9). Two terminal electrical measurements of the silver nanowire revealed nonlinear, history-dependent I-V curves, possibly a result of polarization or corrosion of the individual 30 to 50 nm silver grains that comprise the wires. These examples give initial impressions on how DNA can be utilized as a template to synthesize nanometric and mesoscopic structures. However, the studies have emphasized the importance of fundamental research on how the interaction between DNA and the various binders, such as metal and organic cations, influences the structure and topology of the nucleic acid components involved.

3.5 DNA–protein Interaction for Biotemplating

The examples of Sect. 3.4 clearly indicate the necessity for generating more complex biomolecular architecture, which can be used for the generation of inorganic components by means of biotemplating. An important step in this direction was recently reported, termed *biomolecular lithography*, which took advantage of the sequence-specific binding of conjugates comprised of ssDNA and recA protein. In molecular lithography, the DNA–protein complex is treated with silver ions, which are reduced by aldehyde groups, previously generated within the dsDNA target, thereby forming small silver grains to be subsequently utilized for the wet chemical deposition of gold. This procedure leads to the formation of a conductive wire, which contains an isolating gap, precisely at the position where RecA was bound (Fig. 10a). Therefore, in the molecular lithography, the information encoded in the DNA molecules has replaced the masks used in conventional lithography, while the RecA protein serves as the resist. This approach should work with high resolution over a broad range of length scales from nanometers to many micrometers. Moreover, molecular lithography enables the generation of branch points (three-way junctions) within linear DNA fragments by employing a dsDNA fragment containing a single-stranded end in the initial RecA polymerization step (Fig. 10b). The homologous recombination between RecA conjugate and double-stranded DNA can as well be utilized for the sequence-specific positioning of molecular objects (Fig. 10c). For this, the ssDNA used for polymerization of the RecA monomers is modified with molecular entities, which are functional devices by themselves, or else allow for subsequent binding as such. For instance, gold nanoclusters have been selectively positioned by this approach. Because of the broad scope of molecular lithography, a wide variety of applications might be foreseen.

Semisynthetic DNA–protein nanostructures have been constructed to serve as templates for generating inorganic structures by means of metallization. To this end, oligomeric DNA-STV conjugates **5**, (see Fig. 8), were effectively transformed

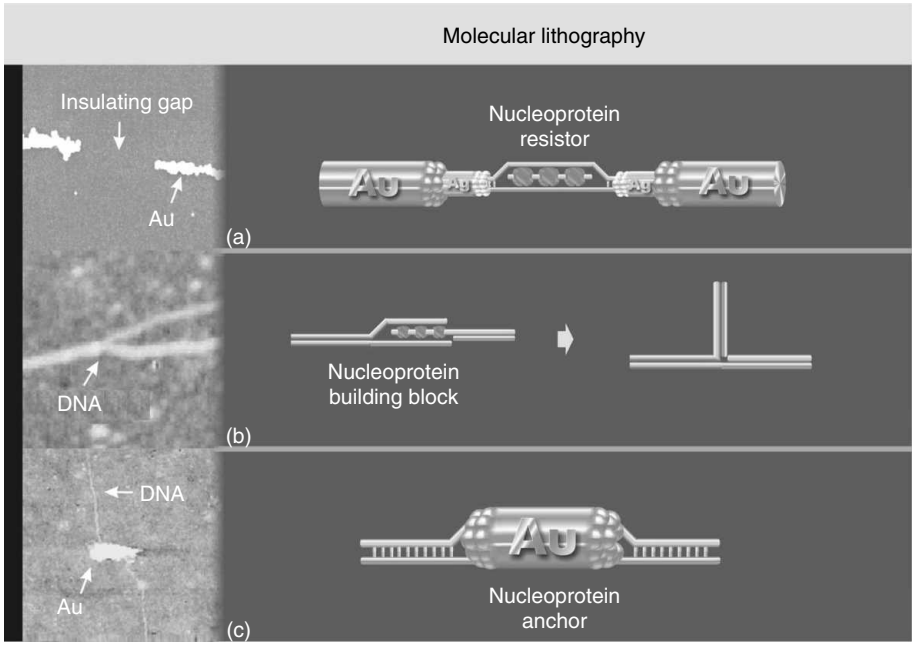

Fig. 10 Molecular lithography. Reprinted with permission from Niemeyer C.M. (2002) Nanotechnology: Tools for the biomolecular engineer, *Science* **297**, 62–63. Copyright 2002 American Association for the Advancement of Science.

into well-defined supramolecular DNA-STV nanocircles **6** by thermal treatment (Fig. 11). Because of their ready availability and well-defined stoichiometry and structure, the nanocircles **6** form the basis of a supramolecular construction kit for generating well-defined DNA-based conjugates. For example, functionalization of **6** with biotinylated haptens allows one to generate hapten conjugates **7**, applicable as reagents in a novel competitive immuno-PCR (cIPCR) assay for the ultra sensitive detection of low-molecular weight analytes. With respect to biomolecular nanotechnology, **5** and **6** can also be used as soft materials topography standardization reagents for AFM. Since the two different biopolymers, DNA and proteins, occur in a highly characteristic, well-defined composition and supramolecular structure, this allows one for direct comparison of, for instance, the deformation properties of the two biopolymers depending on the AFM measurement modes applied.

The conjugates **5** and **6** have also been used as building blocks for generating complex biomolecular nanostructures. As indicated in Fig. 12, networks **5a** and **5b** were generated from the covalent oligonucleotide-STV conjugates **2a** and **2b** respectively, and bis-biotinylated ds-DNA (see AFM images in Figs. 11 and 12). The single-stranded oligonucleotide moieties can be used for further functionalization of **5** by hybridization with complementary oligonucleotide-tagged macromolecules. For instance, oligomers **5a** were transformed into the corresponding

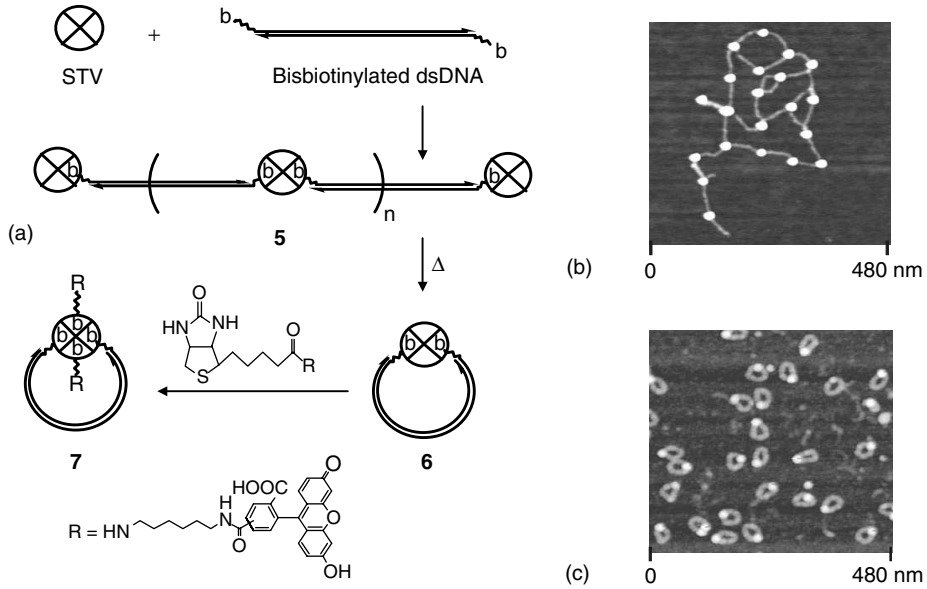

Fig. 11 Nanostructured DNA and STV conjugates. (a) Schematic representation of the self-assembly of oligomeric DNA-STV conjugates **5** from 5′,5′-bis-biotinylated DNA and STV. Note that the schematic structure of **5** is simplified since a portion of the STV molecules function as tri- and tetravalent linker molecules between adjacent DNA fragments (see AFM image b). The supramolecular networks of **5** can be disrupted by thermal treatment, leading to the efficient formation of DNA-STV nanocircles **6** (see AFM image c). The nanocircles **6** can be functionalized by the coupling of biotinylated hapten groups, such as fluorescein (Fsc) to yield nanocircle **7**. For simplification, complementary DNA strands are drawn as parallel lines. The 3′-ends are indicated by the arrow heads. Reprinted with permission from Niemeyer, C.M. et al. (2000) Supramolecular Nanocircles Consisting of Streptavidin and DNA, *Angew. Chem. Int. Ed.* **39**, 3055–3059.

nanocircles **6a**, which can hybridize with analogous circles **6b**, containing a complementary oligonucleotide sequence, to form the nanocircle dimers **8**. The AFM image of the dimeric conjugate **8** indicates the predicted structure (Fig. 12).

3.6 DNA-nanoparticle Conjugates at Tools in Bioanalytics

While protein-coated gold colloids have long been used in bioanalytical techniques, applications of DNA-functionalized gold particles have just been introduced a few years ago by Mirkin and co-workers. The DNA-directed nanoparticle aggregation depicted in Fig. 5 can be used for simple and cheap sensors in biomedical diagnostics, for example, for the detection of nucleic acids from pathogenic organisms. Many analytical applications have already been reported allowing for the detection of nucleic acids in homogenous solutions. In addition, the use of DNA-functionalized nanoparticles in the heterogeneous nucleic acid hybridization with capture oligonucleotides attached to solid supports have recently attracted much attention. Many groups have reported on the DNA-directed

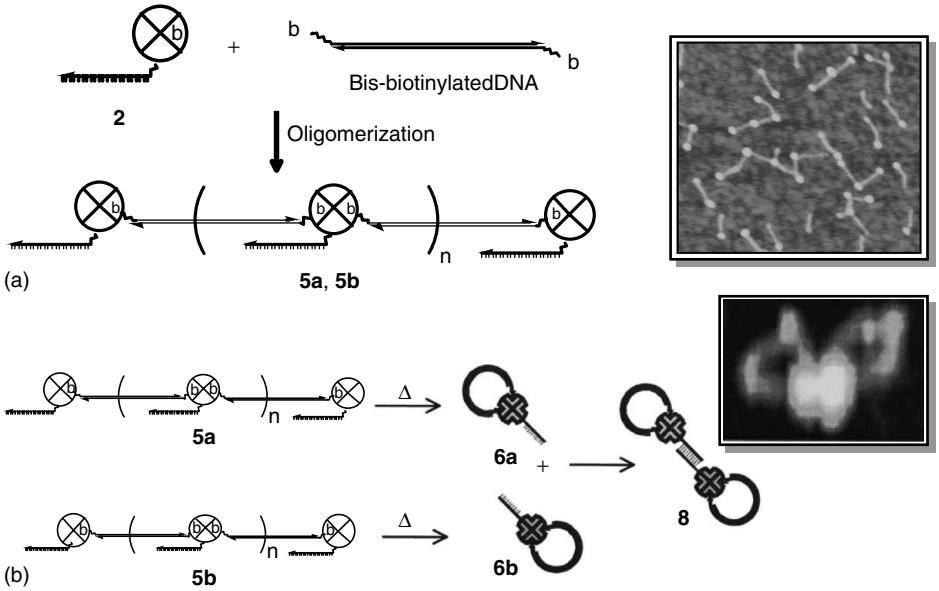

Fig. 12 Construction of supramolecular DNA and STV conjugates. (a.) Networks **5a** and **5b** are generated from covalent oligonucleotide-STV conjugates **2a** and **2b** respectively, containing complementary oligonucleotides. The inset shows a typical AFM image of **5a**. (b) Oligomers **5a**, **b** are transformed into the corresponding nanocircles **6a**, **b**, which hybridize with each other to form the nanocircle dimers **8**. The inset shows a typical AFM imgage of dimer **8**. Reprinted with permission from Niemeyer, C. M., Semisynthetic DNA-Protein Conjugates in C. M. Niemeyer, C. A. Mirkin (Eds.): *NanoBiotechnology: Concepts, Methods, and Applications*, Wiley-VCH, Weinheim 2004, pp. 227–243.

immobilization of gold nanoparticles to form supramolecular surface architecture, and this approach was also adopted to the specific sorting of DNA-functionalized QDs. Particles of different morphology, rods and sticks, have also been assembled by means of DNA hybridization. The specific nucleic acid–mediated immobilization of gold nanoparticles can be utilized for the topographic labeling of surface bound DNA targets. This readily allows for the highly sensitive scanometric detection of nucleic acids in DNA-chip analyses by means of the gold particle promoted reduction of silver ions (Fig. 13), allowing for an about 100-fold increased sensitivity compared to conventional fluorescent DNA detection. In a recent continuation, this approach was adopted to the array-based electronic detection of nucleic acid analytes, using similar setup, as depicted in Fig. 3.

The size-selective light scattering of 50- and 100-nm diameter gold nanoparticles has been used for the two-color labeling of oligonucleotide arrays. An alternative for the simultaneous determination of multiple DNA targets, the use of Raman-active dye-labeled gold nanoparticles, has recently been explored. The gold nanoparticles facilitate the formation of a silver coating that acts as a surface-enhanced Raman scattering promoter for the dye-labeled particles that have been captured by

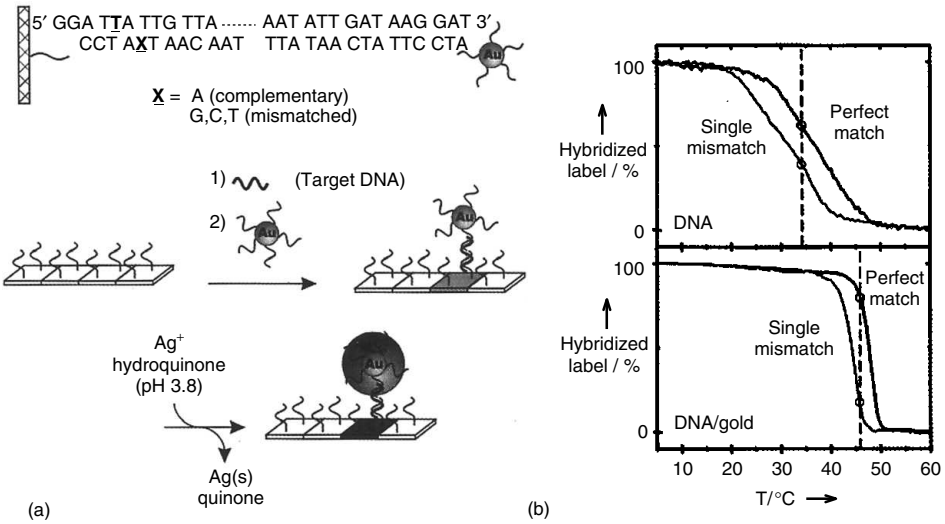

Fig. 13 Scanometric detection of nucleic acids in DNA-chip analyses. Capture oligonucleotides immobilized on glass slides are used for specific binding of target nucleic acids. Oligonucleotide-functionalized gold nanoparticles are employed as probes in solid-phase DNA hybridization detection. Subsequent to a silver enhancement step, the immobilization of the colloidal gold probe is detected by scanning the glass substrate with a conventional flat-bed scanner. Despite its simplicity, this technique allows for an about 100-fold increased sensitivity compared to fluorescent DNA detection. Moreover, owing to the extraordinary sharp melting behavior of the immobilized DNA–nanoparticle networks (see melting curves at the right), this method allows for single-mismatch detection. Reprinted with permission from Taton, T.A., Mirkin, C.A., Letsinger, R.L. (2000) Scanometric DNA array detection with nanoparticle probes, *Science* **289**, 1757–1760.

target molecules and an underlying chip in microarray format. This approach provides the high-sensitivity and high-selectivity attributes of gray-scale scanometric detection, but adds multiplexing and rationing capabilities because a very large number of probes can be designed on the basis of the concept of using a Raman tag as a narrow-band spectroscopic fingerprint. An electrochemical coding technology has been reported for the simultaneous detection of multiple DNA targets. Three encoding inorganic nanocrystal tracers (ZnS, CdS, PbS) were used to differentiate the signals of three DNA targets in connection to stripping-voltammetric measurements of the heavy metal dissolution products. These products yielded well-defined and resolved stripping peaks at the mercury-coated glassy-carbon electrode, thereby enabling femtomole detection limits. The use of colloidal gold nanoparticles also allows for the signal enhancement in the DNA hybridization detection using quartz crystal microbalance, angle-dependent light scattering, and SPR (see Sect. 2.3). DNA-functionalized CdS nanoparticles were used for the photoelectrochemical detection of nucleic acid hybridization. To this end, an array of QDs was assembled at the surface of an electrode using the specific hybridization of complementary DNA fragments. Upon irradiation, a photocurrent was generated, which was proportional to the amount of target DNA.

DNA-tagged proteins have been immobilized at DNA-coated gold nanoparticles by specific nucleic acid hybridization. This approach has several advantages over the conventional methods to adsorb proteins to colloidal gold. The biofunctionalized nanoparticles not only retain the undisturbed recognition properties of the proteins immobilized but they also reveal an extraordinary stability, which even allows for regeneration of the DNA-coated gold particles. The bioinorganic hybrid components were used as reagents in sandwich immunoassays for the detection of proteins using the gold particle promoted silver development. This allowed the spatially addressable detection of fmol-amounts of chip-immobilized antigens. By utilizing oligonucleotide-modified gold nanoparticles encoded with sequences that act as biobarcodes, one can screen for multiple target polyvalent proteins simultaneously in one solution. This concept was demonstrated with two types of detection formats, a homogeneous assay and one based on oligonucleotide microarrays. With such an approach, one can prepare a large number of barcodes from synthetically accessible oligonucleotides. For instance, a 12-mer sequence offers 4^{12} possible barcodes.

4
Magnetic Nanoparticle Conjugates

4.1
Magnetic Nanoparticles in Biomedical Sciences

Nanoparticles comprised of superparamagnetic materials, for example, iron oxide, have already been developed in the early 1990s by Weissleder and coworkers. The particles are typically 5–10 nm in diameter, they possess a half-live of about 90 min in blood, and the major potential applications are as intravenous contrast agents for the lymphatic system, bone marrow contrast agent, long-half-life perfusion agent for brain and heart, and as a magnetic moiety in organ-targeted superparamagnetic contrast agents for magnetic resonance imaging (MRI). With respect to the latter type of applications, in particular, attachment of biomolecular recognition groups to the surface of the inorganic nanoparticles greatly enhances the specificity of targeting. For instance, dextran coated superparamagnetic iron oxide particles were derivatized with a peptide sequence from the HIV-tat protein to improve intracellular magnetic labeling of different target cells. The particles were internalized into lymphocytes over 100-fold more efficiently than nonmodified particles. Labeled cells are highly magnetic and can be retained on magnetic separation columns. This method has great potential for in vivo tracking of magnetically labeled cells by MRI and for recovering intracellularly labeled cells from organs.

Paramagnetic nanoparticles are also being investigated for the treatment of cancer. Biocompatible dextran or silan-coated superparamagnetic magnetite nanoparticles can be incorporated into malignant cells by endocytosis. The intracellular magnetic fluids are excited with AC magnetic fields, leading to an increase in the local temperature, thereby inducing hyperthermia. It has been demonstrated that magnetic fluid hyperthermia (MFH) affects mammary carcinoma cells *in vitro* and *in vivo*.

With respect to biosensing, superparamagnetic iron oxide nanoparticles have been developed that can be used as magnetic relaxation switches to detect molecular interactions in the reversible

self-assembly of disperse magnetic particles into stable nanoassemblies. Monodisperse magnetic nanoparticles conjugated with complementary oligonucleotide sequences self-assemble into stable magnetic nanoassemblies, resulting in a decrease of the spin–spin relaxation times of neighboring water protons. When these nanoassemblies are treated with a DNA- cleaving agent, such as restriction enzymes, the nanoparticles become dispersed, switching the T2 of the solution back to original values. As shown for four different types of molecular interactions (DNA–DNA, protein–protein, protein–small molecule, and enzyme reactions), magnetic relaxation measurements can be used to detect these interactions with high efficiency and sensitivity. Since the magnetic changes are detectable in turbid media,, for example, whole-cell lysates without protein purification, magnetic nanosensors might be used in a variety of biological applications, such as in homogeneous assays, miniaturized microfluidic systems, as affinity ligands for the rapid and high-throughput magnetic readouts of arrays, as probes for magnetic force microscopy, and for *in vivo* imaging.

4.2 Magnetic Switching of Nanoparticle Devices

Magnetic fields have also been used for the remote electronic control of DNA hybridization of gold nanoparticle–DNA molecular beacon conjugates. DNA beacons are ssDNA molecules, which form an intramolecular hairpin-loop structure. Both ends are chemically modified with a fluorophor and a quencher dye, the latter of which, due to close spatial proximity, effectively quenches the fluorescence. Upon hybridization with nucleic acid targets, containing a sequence stretch complementary to the loop region of the beacon, the quencher is spatially removed from the fluorophor, leading to a strong enhancement in fluorescence. A novel class of molecular beacons has been introduced, in which the organic quencher dye was replaced by a gold metal cluster. The quenching efficiency was determined to be about 99.5%, indicating that the fluorescent signal of the beacon increases about 200-fold upon hybridization with complementary target. This type of gold-oligomer-dye hybrid beacons allowed one to detect single base mutations more efficiently than with conventional molecular beacons. Similar gold nanoparticle–DNA molecular beacon conjugates have been exploited for the remote electronic control of DNA hybridization. Inductive coupling of a radio frequency magnetic field (RFMF) with a frequency of 1 GHz to the 1.4-nm metal nanocrystal, which functions as an antenna in the DNA constructs, the local temperature of the bound DNA is increased, thereby inducing denaturation while leaving surrounding molecules relatively unaffected. Since inductive heating has already been applied to the treatment of cancer cells with magnetic field induced excitation, the use of gold nanocrystal–DNA conjugates should allow extension of this concept. For instance, complex operations, such as gene regulation, biomolecular assembly, and enzymatic activity, of distinct portions of nucleic acids or proteins might be controlled, while the rest of the molecule and neighboring species would remain unaffected. Moreover, because the addressing is not optical, this technology would even be applicable in highly scattering media.

The magnetic switching of biomolecular functionality has been demonstrated in a couple of examples using micrometer-sized superparamagnetic iron

oxide particles was demonstrated by Willner and colleagues. As an example, magnetic-field-stimulated ''ON'' and ''OFF'' biochemiluminescence was accomplished by electrocatalyzed reduction of naphthoquinone-functionalized magnetic particles in the presence of a biocatalytic peroxidase/luminol system. The dual biosensing by magnetocontrolled bioelectrocatalytic analysis of glucose and lactate by the enzymes glucose oxidase and lactate dehydrogenase was conducted by using ferrocene-functionalized electrodes and enzyme-modified iron oxide magnetic particles. Wang et al. have demonstrated the magnetic triggering of the electrical DNA detection, realized through a magnetic collection of assemblies, formed by specific hybridization of oligonucleotide-gold nanoparticles with microbeads containing complementary oligonucleotides. The assemblies are subjected to silver development using hydrochinon, and the resulting conglomerate is positioned on an electrode by an external magnetic field. The chronopotentiometric hybridization signals allowed the detection of small amounts of target DNA. The development of tiny nanometer-sized functionalized magnetic particles will even increase the scope of applications in nanobiotechnology and biomedical diagnostics.

5
Other Applications

5.1
Transfection

It is well established to use gold particles as carriers for the delivery of double-stranded DNA in the so-called *gene gun* technology. In this method, plasmid DNA of a typical length of several 1000 base pairs is adsorbed to gold or tungsten colloids, which have a typical size of about 500 nm to several micrometers. The DNA- or RNA-coated particles are loaded into a gun-like device in which a low-pressure helium pulse delivers the particles into virtually any target cell or tissue. As an advantage of this technique, one does not have to remove cells from tissue in order to transform cells. The particles penetrate the cells and release the DNA, which is diffused into the nucleus and, for instance, incorporated into the chromosomes of the organism. Since its development in the mid-1980s, the gene gun technology has led to innumerous examples demonstrating the tremendous potential of this method for ''biolistic'' transfection of organisms as well as for DNA immunization. The latter technique, also known as *DNA vaccination* or *genetic immunization*, is a vaccine technology that can be used to stimulate protective immunity against many infectious pathogens, malignancies, and autoimmune disorders in animal models. Plasmid DNA encoding a polypeptide antigen is introduced into host cells, for instance, via gene gun particle bombardment, where it serves as a template for the high-efficiency translation of its antigen. This leads to an immune response, which is mediated by the cellular and/or humoral immune system and is specific for the plasmid-encoded antigen.

5.2
Nanoparticles as Model Systems

Two general aspects of metal and semiconductor nanoparticles make them suitable model systems for the study of basic biological phenomena. On the one hand, their size matches with the macromolecular components employed in living systems. Proteins, nucleic acid fragments and their

supramolecular complexes, such as the nucleosome, the various complexes involved in DNA replication and transformation, and the ribosome, have typical dimensions in the range of 2 to 200 nm. On the other hand, nanoparticles of inorganic materials are the basic building blocks in biomineralization, a fundamental biological process in which nature chemically generates form by means of genetic instructions. It is thus not surprising that the current advances in the study of metal and semiconductor nanoparticles has led to their consideration as model systems for both, the study of the interactions between proteins and nucleic acids, and also for the understanding of the basic principles of biomineralization. This type of applications have been recently reviewed elsewhere.

6 Conclusions and Perspectives

Although the chemical coupling of biomolecules and inorganic materials can be achieved with a variety of methods, there is still a great demand for mild and selective coupling techniques, which allow for the preparation of thermodynamically stable, kinetically inert, and stoichiometrically well-defined bioconjugate hybrid nanoparticles. The first steps to using these hybrid compounds as building blocks for the bottom-up assembly of sophisticated nanostructured architecture have already been achieved using protein- or nucleic acid–based recognition elements. Directed evolution, already applied to tailor protein linkers, should be applicable to generate novel nucleic acid–based linkers. It seems safe to predict that the tremendous advances in the development of artificial nucleic acid receptors, aptamers selected to specifically recognize any target structure, will soon be applied to the *de novo* generation of nucleic acid receptors, capable of recognizing inorganic surfaces. Consequently, combinations of the two fundamental biological systems, nucleic acids and proteins, are very promising to synergistically cooperate and allow for novel functions and applications. Another crossover of biotechnology and materials science concerns the utilization of the chemical and topographical properties of biological components for templating the spatial assembly of organic and inorganic components to form nanometer- and micrometer-sized elements. Although commercial applications are rare at current state, the interdisciplinary work has a great potential for generating advanced materials, which might lead to novel devices for sensing, signal transduction, catalysis, as well as for new biocompatible materials and interfaces currently being developed for biomedical sciences and tissue engineering. In addition to long-term perspectives, today's nanoparticles are already used in bioanalytical applications or as model systems to solve biological problems.

The future development of the joint venture of biotechnology and material sciences will profit from the rapid current advances of chemistry as a central science. In addition, the current genome and proteome research will also be beneficial for this field, since it provides data, which will allow us to produce even more suitable biocomponents. This might open the door to nanosensors, catalytic and light-harvesting devices, ultra fast molecular switches and transistors, supramolecular mediators between electrical and living systems and other bio- and optoelectronic parts. Clearly, we are still far off from the fabled autonomous nanomachines

that heal wounds and perform surgery in a living organism. However, at the beginning of this new century, one should remember the dramatic development total organic synthesis has undergone from the early 1900s to the race for ''molecular summits'' in the late 1990s. A similar rate of progress in supramolecular sciences at the interface of biotechnology and materials research promises plenty of excitement from future developments.

Keywords

Holocentric, Holokinetic
A chromosome in which kinetochore forms along the length of the chromosome.

Systemic RNAi
Non-cell-autonomous action of an interfering RNA.

The nematode worm *Caenorhabditis elegans* is a major model organism for studies in genetics, cell biology, neurobiology, and development. The use of *C. elegans* as a model organism began in the 1950s. The cellular basis of the development and neuroanatomy of *C. elegans* have been described in detail. Studies of *C. elegans* have elucidated the genetic basis of apoptotic cell death, axon guidance, aging, and RNA interference. The *C. elegans* genome is one of the smallest known for any animal and was the first animal genome to be completely sequenced. The number of genes in the worm genome is comparable to that of other larger animals, suggesting that although *C. elegans* is small, it has comparable biological complexity to other animals. The functions of most *C. elegans* genes are not known. *C. elegans* is well suited to both forward and reverse genetic manipulations of the genome. Postgenomic studies are continuing to explore the biological complexity of *C. elegans*.

1 Overview of *C. elegans* Biology

1.1 *C. elegans* as a Biological Model

For over forty years, the nematode *Caenorhabditis elegans* (*C. elegans*) has been used as a model for studies of animal development and behavior. Systematic genetic and anatomical analysis of *C. elegans* was begun by Brenner and his group in 1965. Currently, several hundred laboratories around the world use *C. elegans* for studies into the basic mechanisms of animal development, physiology, cell biology, and behavior.

Many advantages of *C. elegans* as a biological model result from its small size and cell number. Adult hermaphrodite animals are 1-mm long, transparent, and contain 959 somatic cells. The pattern of cell divisions, or cell lineage, is largely invariant between individuals. This has allowed the complete *C. elegans* cell lineage (zygote to adult) to be reconstructed directly from observations of development in living animals. The anatomy of *C. elegans*, including the synaptic connectivity of the nervous system, has been completely reconstructed from electron micrographs of serial sections. *C. elegans* remains the only animal for which the development and ultrastructure have been so completely described.

The reproductive biology of *C. elegans* is highly suited for genetic analysis. *C. elegans* reproduces sexually as a self-fertilizing hermaphrodite, allowing populations to be maintained without crossing. However, crossing is essential for genetic manipulations, and fortunately *C. elegans* males can cross-fertilize hermaphrodites. The generation time is short (3 days), and laboratory culture requirements are relatively simple. *C. elegans* stocks can be preserved cryogenically.

The genome of *C. elegans* is one of the smallest known for an animal (100 million base pairs, Mbp) and it was the first animal genome to be fully sequenced, in 1998. The *C. elegans* genome is estimated to contain over 21 000 genes, 40% of which have recognizable homologs in humans. The functions of most *C. elegans* genes are not known.

Studies of *C. elegans* have yielded insight into many areas of biology. The pioneering analysis of *C. elegans* development and programmed cell death by Brenner, Sulston, and Horvitz, was recognized by the award of the 2002 Nobel Prize in Physiology or Medicine (see Nobel lectures by Horvitz and Sulston). *C. elegans* studies have also played key roles in advancing our understanding of neuronal axon guidance, of the genetic control of aging, and in the development of RNA interference.

Detailed information on the biology of *C. elegans* is available in two monographs: *The Nematode Caenorhabditis elegans*, edited by W.B. Wood, and *C. elegans II*, edited by D. Riddle and others. These books should be consulted for a more detailed treatment of the topics in this article. More current descriptions of *C. elegans* biology are in preparation as an online supplement to Wormbase. Two books of methods related to *C. elegans* work have been published (see books edited by Hope, and by Shakes and Epstein).

1.2 Taxonomy, Evolution, and Ecology

C. elegans is a member of the phylum *Nematoda* (roundworms). Nematodes comprise one of the five most successful animal phyla in terms of number of organisms and number of species. The nematode body plan is highly conserved and *C. elegans* is representative of the group. *C. elegans* is a member of the order Rhabditida, composed mostly of nonparasitic terrestrial species. Phylogenetic analysis suggests that *C. elegans* is closely related to parasitic nematodes of the order Strongylida, and thus *C. elegans* studies may have particular relevance to these nematodes.

Several other species within the genus *Caenorhabditis* are the subject of active investigation. *Caenorhabditis briggsae* (*C. briggsae)* is morphologically hard to distinguish from *C. elegans*; in the older literature *briggsae* and *elegans* were often mistaken for one another. Remarkably, despite their similar morphology the *C. briggsae* and *C. elegans* genomes are quite divergent; the extent of divergence has been described as being comparable to that between the human and mouse genomes. Because there is almost no fossil record for nematodes, and because rates of gene divergence appear to differ between animal groups, the time of divergence of the two species is hard to estimate.

The genomes of three additional *Caenorhabditis* species are being sequenced (*C. remanei, C. japonica*, and *Caenorhabditis* sp. CB5161). The comparative genomic analysis of these closely related species is expected to be a rich resource for understanding the structure and function of the genome. Genomic or

EST sequencing projects are in progress for several parasitic nematodes.

C. elegans is typically found in soil, especially in mushroom compost. *C. elegans* is a cosmopolitan species; isolates have been found throughout the temperate northern hemisphere. The ''natural'' food of *C. elegans* is not known, but may include soil bacteria, yeast, and other microorganisms such as cellular slime molds. Different wild isolates display frequent sequence polymorphisms among themselves and relative to the reference wild type N2. As a result of genome sequence information, mutations isolated in the N2 background can usually be rapidly mapped with respect to single-nucleotide polymorphisms (SNPs) between N2 and wild isolates such as the Hawaiian strain CB4856.

1.3 Sexual System, Life Cycle, and Developmental Stages

C. elegans reproduces sexually. There are two sexes, a self-fertilizing hermaphrodite and a cross-fertilizing male. (A sexual system involving males and hermaphrodites is known as *androdioecy*.) Hermaphrodites make sperm during larval development and later switch to making oocytes as adults. Hermaphrodites make about 300 sperm, so the self-progeny brood size of a single hermaphrodite is about 300. Males make ~2000 sperm and so can sire many more cross progeny.

Although androdioecy is also found in other nematode species, including *C. briggsae*, the more common and presumably ancestral sexual system is gonochoristic (male–female), as found in *C. remanei* and all other members of the *Caenorhabditis* genus. Hermaphrodites may be thought of as modified females: they have a female soma and have developed a way to modulate the sex of their gametes, allowing self fertilization. Single-gene mutations are known, that prevent formation of sperm in hermaphrodites, essentially returning them to an obligate male–female system; *C. elegans* can be converted to a variety of sex-determination systems by genetic manipulations.

Fertilization occurs in the hermaphrodite uterus. Fertilized eggs are laid after about 2 hours of development; embryogenesis is complete about 11 hours later at 20 °C. The egg hatches into the first larval stage (L1). Larval development takes 2 days, and consists of the four larval stages L1 to L4. Between each larval stage the old cuticle is shed (molting) and a new cuticle is formed. The L4 molts into an adult, which begins to lay eggs a few hours afterwards. From egg to egg at 20 °C takes about 3.5 days.

The sequence of cell divisions in *C. elegans* development is largely invariant from individual to individual. This, together with their small size and transparency, allowed the entire cell lineage (zygote to adult) to be reconstructed from observations of living animals. Each cell in an animal can thus be named both according to its lineal ancestry and according to its differentiated fate. A comprehensive online guide to *C. elegans* anatomy is at www.wormatlas.org.

1.4 Genetics and Nomenclature

Modern *C. elegans* genetic analysis began with Brenner's choice of the Bristol strain of *C. elegans* as his reference wild type, which he designated N2. Most subsequent genetic work has been in the N2 strain background or its derivatives. Genetic drift from the original stock of N2 has been minimized by cryogenic

preservation of stocks. A public collection of wild type and mutant stocks is maintained by the (CGC) *Caenorhabditis* Genetics Center (http://biosci.umn.edu/CGC/CGChomepage.htm).

All *C. elegans* genes are given a ''gene model'' name by Wormbase. For example, cosmid clone K03D10 contains multiple genes, either experimentally confirmed or only predicted, and numbered as K03D10.1, K03D10.2, and so on. Different splice variants are indicated by subscripts, for example, K03D10.1a, K03D10.1b.

Subsets of genes have been assigned official ''three-letter'' names by the *Caenorhabditis* Genetics Center. Three-letter names may indicate the mutant phenotype of the gene or the nature of the predicted gene product. Genes that were first identified by their mutant phenotype are named after it, for example, ''dumpy'' (*dpy*), ''blistered'' (*bli*), uncoordinated (*unc*), and variably abnormal (*vab*). Many genes mutate to similar (but not identical) phenotypes, and so are put in the same general class with different numbers (*dpy-1, dpy-2,* etc.). Alternatively, some genes are identified by their sequence similarity to a gene in another organism. For example, *kal-1* is similar in sequence to the gene mutated in the X-linked form of Kallmann syndrome.

Mutations have unique names consisting of the laboratory code and a number. For example, the first mutant to be found in Brenner's genetic screens (in October 1967) had a dumpy phenotype. The name of the mutation causing the mutant phenotype is *e1*. The name of the gene affected by this mutation is *dpy-1*. Thus, the full name of the mutation is *dpy-1(e1)*. The *e* prefix indicates the laboratory in which the mutation was isolated. The wild-type (N2) version of a gene is written as *dpy-1(+)*.

All *C. elegans* strain names have a two-letter or three-letter lab code (e.g. MT for the Horvitz laboratory at MIT) and a number. Each strain has a unique name to avoid confusion. The genotype is the complete listing of all the mutations in the strain. For example, a very useful strain has the name MT465 and bears mutations on chromosomes I, II, and III. The full genotype of MT465 is *dpy-5(e61) I*; *bli-2(e768) II*; *unc-32(e189) III*. The mutations *e61*, *e768*, and *e189* cause dumpy, blistered, and uncoordinated phenotypes respectively.

C. elegans nomenclature distinguishes the gene name, the mutant phenotype, and the protein (or RNA) product. Genes and mutations are written in lower-case italics (*kal-1*, *vab-1*), while phenotypes are in Roman typeface with initial letters capitalized (e.g. Vab, Unc). Protein products are written in upper-case (e.g. KAL-1, PTP-3A, PTP-3B).

A more detailed account of *C. elegans* nomenclature is available online at the CGC web site.

2 *C. elegans* Genomics

2.1 Genomes and Informatics

The *C. elegans* genome was the first animal genome to be sequenced fully. An overview of *C. elegans* genomic features was published in 1998 when most of the sequence had been completed. The last sequence gaps of the genome were completed in late 2002. However, analysis and annotation of the sequence is a continuing process that will occupy researchers for many years. The genomic sequence

information and annotations are available online. Wormbase (www.wormbase.org) is a public repository of genomic, genetic, and anatomical information. The genomic sequence can also be searched at the University of California Santa Cruz genome browser (genome.ucsc.edu) and at several other online sites. The completion of a draft *C. briggsae* genome sequence in 2003 allows a global comparison with the now-finished *C. elegans* genome, on which the discussion below is based.

2.2 Protein-coding Genes and the Proteome

The *C. elegans* genome is estimated to contain 19 775 protein-coding genes, of which 2376 display alternative splicing, resulting in a predicted proteome of 22 151 proteins (Wormpep release 127, July 2004). 75% of these genes are supported by partial or complete experimental (EST) data; the remainder are predicted but not yet confirmed. Systematic projects are underway to generate a complete set of functional open reading frames (the ORFeome) and to test all known *C. elegans* proteins in two-hybrid interaction screens. One notable feature of the *C. elegans* proteome is the large number (>700) of seven-pass transmembrane receptors, many of which are thought to function as olfactory receptors. This gene family has expanded almost twofold in *C. elegans* relative to *C. briggsae*, for reasons unknown.

The distribution of genes within the worm genome exhibits several nonrandom features on various scales. In addition to being organized into operons (see below), genes of the same family are often locally clustered, probably as a result of tandem duplications in evolution. Where genes of different families are coexpressed in the same tissue, they also show local clustering into groups of 2 to 5 genes. Genes involved in reproduction show longer-range clustering. Interestingly, the latter clusters are not conserved in *C. briggsae*, suggesting that they have recently evolved. Finally, more conserved genes with essential functions tend to be found in the centers of chromosomes, whereas more diverged genes are enriched in chromosomal arms. Such chromosome-wide patterns of gene distribution have not so far been observed in other organisms.

2.3 The Noncoding RNA World

The *C. elegans* genome contains approximately 890 noncoding (nc) RNA genes, including approximately 600 tRNAs. Ribosomal RNAs are generated from two tandem arrays: an array of ~100 to 150 copies of the 18S, 5.6S, and 26S genes on chromosome I, and an array of 100 copies of the 5S repeat (which includes the SL1 trans-spliced leader) on chromosome V. Most other conserved ncRNAs are present in the *C. elegans* genome, including snRNAs U1, U2, U5, and SRP. Some ncRNAs have not yet been found; these may truly be absent (e.g. U12 snRNAs) or may be hard to detect computationally (e.g. telomerase RNAs). Mutations in U1 snRNAs have recently been identified as informational suppressors of mutations affecting the conserved +1G position of introns.

The *C. elegans* genome contains numerous small noncoding RNAs, generally known as microRNAs or miRNAs. The first two animal miRNAs, *lin-4* and *let-7*, were discovered through genetic analysis of developmental control genes known as heterochronic genes. *lin-4* and *let-7* are short (22 nucleotide) RNAs processed from longer hairpin precursors by the endonuclease DCR-1/Dicer. Both RNAs form

duplex structures by complementary base pairing with target sequences in the 3′ UTRs of other transcripts. Despite their short sequence, *let-7* orthologs have been found in many other animals, suggesting that *let-7* function is conserved in animal evolution.

From computational and experimental data, the total number of miRNA genes in the genome has been estimated to be approximately 100 to 120. Almost all *C. elegans* miRNAs are conserved in *C. briggsae*; about 30% appear to be conserved in insects or vertebrates. An additional class of ''tiny noncoding RNAs'' consists of short RNAs that do not appear to be processed from a longer precursor. Experimental searches for such short RNAs have also revealed antisense RNAs from hundreds of genes, suggesting that gene regulation by antisense RNA may be widespread.

2.4 Whole-genome Analyses of Gene Expression

Several approaches have been used to analyze global patterns of gene expression in *C. elegans*. Systematic sequencing of cDNAs has generated a database of expressed sequence tags (ESTs). ESTs, as well as experimentally defining gene structures, have been used in genome-wide *in situ* hybridization screens of expression patterns (available online at nematode.lab.nig.ac.jp).

Whole-genome DNA microarrays have been used to profile global gene expression patterns across developmental stages, tissue types, physiological conditions, and in different mutant backgrounds. Such gene profiling approaches have provided critical insights into the transcriptional programs underlying the development of specific tissues, such as the germline, of organs such as the pharynx, and of metabolic processes. Data from several hundred such microarray experiments have been combined by clustering algorithms to develop a ''gene expression topological map'' that represents the correlation in gene expression differences between different conditions. Clusters on this gene expression map can represent either tissues (e.g. neurally expressed genes) or biochemical processes.

2.5 Transposons and Repetitive Elements

Approximately 16% of the *C. elegans* genome consists of repetitive elements. The largest repeat family consists of ~3000 copies of a 439-bp element, forming 1.3% of the genome. The slightly larger size of the *C. briggsae* genome (104 Mbp) is solely due to expansion of certain repeat families.

C. elegans contains at least six families of active transposons, designated Tc1 through Tc5, and Tc7. Tc1 and Tc3 are members of the *mariner* subfamily and their mechanisms of transposition have been studied in detail. In the reference wild-type Bristol N2, there are 32 copies of Tc1. Although most of its Tc1 elements are intact, the N2 strain actively represses transposition in the germline by an RNA interference-related process. Other wild isolates such as the so-called *Bergerac* strains contain hundreds of Tc1 elements and are active for transposition. Strains in which transposition is elevated allow transposon-mediated mutagenesis both in forward and reverse genetic approaches. Nonnative elements such as the insect transposon *Mos1* can transpose in *C. elegans* and have been successfully used in transposon-tagging mutageneses.

3
C. elegans Chromosome Structure

3.1
The Chromosomes

C. elegans has five autosomes (I-V) and a sex chromosome (X). Hermaphrodites have two X chromosomes and males have one; the wild-type karyotype is therefore 12 for hermaphrodites (XX) and 11 for males (XO). Cytologically, *C. elegans* chromosomes appear as uniform rods a few microns in length and cannot be distinguished without the use of sequence-specific probes. As discussed below, *C. elegans* chromosomes have delocalized centromeres; no specific DNA sequences have yet been shown to be required for *C. elegans* centromere activity.

C. elegans telomeres consist of several kilobases of tandem repeats of the sequence TTAGGC, similar to those of other organisms. These repeats are probably sufficient for telomeric function, as the subtelomeric sequences appear to be unique. The telomerase enzyme has not been defined in *C. elegans*; some proteins have been shown to pay roles in telomere maintenance or replication.

Unlike mammalian chromosomes, *C. elegans* chromosomes lack a defined centromere. Instead, a kinetochore assembles uniformly along the entire length of the chromosome during mitosis. Such chromosomes are termed *holocentric* or *holokinetic*. Holocentric chromosomes appear to be characteristic of nematodes, and are also found in some insects and plants. The holocentric nature of *C. elegans* chromosomes probably underlies the ability of *C. elegans* cells to segregate exogenous extrachromosomal DNA with some fidelity. Despite these differences, the mitotic kinetochore resembles that of other eukaryotes in ultrastructure. Several components of the *C. elegans* kinetochore have been identified.

3.2
Transgenes and Extrachromosomal Arrays

C. elegans cells can propagate extrachromosomal ''arrays'' of exogenous DNA (notated as *Ex*, e.g. *juEx600*). Such arrays are the predominant means of introducing transgenes into *C. elegans*. Arrays are generated by injecting DNA into the syncytial or cellular gonad of a parental hermaphrodite. Arrays form in a semi-random process in the germ cells that give rise to the progeny of the injected animal; a single parent can give rise to multiple transgenic progeny, each with a different version of the transgenic DNA. Such arrays are replicated and transmitted with variable fidelity in mitosis and meiosis. Although these observations suggest that there is no specific sequence requirement for a centromere, the low fidelity of array transmission could reflect a subtle requirement for specific sequences for full centromeric function. Alternatively, arrays may be transmitted poorly because they are much smaller than normal chromosomes.

Little is known of the structure of *C. elegans* extrachromosomal arrays – it is not known whether arrays are linear or circular DNAs. Southern blotting experiments suggest that most stable arrays contain several hundred copies of the injected DNA arranged in tandem repeats. However, many copies may be nonfunctional or otherwise rearranged, so the effective copy number of a transgene is likely to be lower. Extrachromosomal arrays are usually integrated into the genome by a random chemical or radiation mutagenesis to induce double-strand breaks, to form integrated

arrays (denoted *Is*, e.g. *juIs1*). An alternative transformation method that can yield low-copy or single-copy transgenes is to introduce DNA by ballistic transformation; such DNA is integrated nonhomologously into a chromosome. Although there have been reports of homologous recombination in *C. elegans*, such events are at present too inefficient for routine use in gene targeting or replacement.

3.3 Meiosis and Recombination

Cytologically, *C. elegans* meiosis resembles that of other organisms. The stages of meiosis correlate with the development of germline nuclei in the gonad and can be readily distinguished by cytology of gonadal preparations. *C. elegans* chromosomes display several unusual features in their genetic organization that relate to the control of recombination in meiosis. First, despite wide variation in physical size (13.7 Mbp to 20.9 Mbp), all chromosomes are of the same genetic length (~50 centiMorgans). This reflects a chromosome-wide interference process that ensures that each bivalent undergoes, on average, one and only one crossover event. Second, recombination rates are not uniform over the chromosomes. Ninety percent of crossovers occur in the terminal one-third portion of chromosomes: thus, genes in the center of each chromosome appear genetically ''clustered'' whereas genes on the flanking arms appear dispersed. The unequal distribution of crossovers reflects both cis-acting sequences (e.g. recombination occurs preferentially in introns) and trans-acting factors (e.g. *rec-1*). Third, specific chromosomal regions are required for homolog pairing and, consequently, for crossovers. Each chromosome has one end that acts as its ''pairing center.'' The existence of these regions explains why *C. elegans* reciprocal translocation chromosomes can act as crossover suppressors. Instead of forming a more typical tetravalent structure that maximizes pairing using sequence identity, *C. elegans* translocation heterozygotes probably form two separate bivalents using the two pairing centers.

4 The Nucleus and Gene Expression

4.1 Chromatin and Transcription

Eukaryotic chromatin is organized into states that allow or prevent active transcription. These states can be stably inherited through cell divisions, or can be ''erased'' by chromatin-remodeling complexes. The organization of *C. elegans* chromatin plays a key role in the developmental distinction between somatic and germline tissue. The X chromosome is modified selectively, lacking the modified histones associated with active transcription, and being enriched in histones associated with silenced chromatin. The X chromosome is generally depleted of genes expressed in the germline. Proteins involved in the germline-specific repression of X-linked genes are also required for somatic repression of developmental control genes, indicating a common mechanism in the control of these chromatin states.

Specification of the silenced state of germline chromatin is an essential and early part of germline development. Two factors are known to play critical roles in germline specification: the zinc finger protein PIE-1 and the perinuclear organelles

known as P granules. PIE-1 appears to function to protect the early germline from the activity of a chromatin-remodeling complex related to the vertebrate NuRD complex. This NuRD-like complex is active in somatic cells and is required for determination of somatic cell fates; loss of NuRD function transforms somatic cells into germline-like cells.

The unequal dosage of X-linked genes between XX and XO animals is compensated for by the twofold repression of X-linked gene expression in XX hermaphrodites. The protein complex responsible for this chromosome-specific repression has been characterized and is related to protein complexes required for chromosome condensation during mitosis and meiosis.

4.2 Splicing and mRNA Processing

Most aspects of mRNA processing in *C. elegans* resemble those of other eukaryotes, with some significant differences. First, *C. elegans* introns are unusually small; several confirmed introns are less than 40 bp in length. *C. elegans* introns also lack a defined branch site or polypyrimidine tract. These differences suggest that *C. elegans* spliceosome assembly may differ from that in yeast or vertebrates.

Second, in addition to conventional (cis) splicing, *C. elegans* transcripts frequently undergo trans-splicing, in which a ''spliced leader'' RNA is spliced to the 5′ end of an mRNAs. The trans-splicing reaction resembles that of *cis*-splicing. The most common leader sequence is the 22 nt SL1 spliced leader, which is donated from a 100 nt precursor, itself transcribed from the 5S ribosomal RNA tandem repeats. The SL1 leader provides the trimethylguanosine cap. SL1 function is essential for viability. SL1 addition is often very close to the initiator methionine codon, so it may have some role in translation.

The third and most unusual aspect of *C. elegans* mRNA processing is that about 15% of genes are transcribed in polycistronic messages from clusters of two to eight adjacent genes known as operons. Transcription of an operon begins at the promoter of the 5′-most gene. More 3′ genes are transcribed into a polycistronic message that is processed by conventional 3′-end formation and trans-splicing to make monocistronic mRNAs. Notably, 3′ messages are trans-spliced to a second class of spliced leader, known as SL2. SL2 leaders are made by a dispersed family of 18 genes and, unlike SL1, show some sequence variation.

Most operons are highly conserved between *C. elegans* and *C. briggsae*. Operons may be present throughout the nematode phylum, and may be characteristic of animals that exhibit trans-splicing. Polycistronic organization presumably facilitates coordinate expression of the genes in an operon. Some operons consist of genes with biochemically related functions, so knowledge of the function of one gene in an operon can sometimes give clues about the functions of others. However, for most operons the functional relationship of the genes is not so clear-cut. Relative to the genome as a whole, operons are enriched in essential genes with functions in gene expression, RNA metabolism, or mitochondrial physiology.

4.3 Translation

Analysis of translation in *C. elegans* has focused largely on translational control of

gene expression. The cytoplasmic translational apparatus appears typical of eukaryotes; however, components of the mitochondrial translational apparatus are the smallest known for eukaryotes. For example, *C. elegans* mitochondrial tRNAs lack some of the normal structural features of tRNAs. The *C. elegans* nuclear genetic code is standard. *C. elegans* encodes a selenocysteine tRNA that recognizes UGA codons in certain contexts. *C. elegans* genes exhibit limited synonymous codon bias that correlates with expression levels. Codon bias is less pronounced in longer genes, for unknown reasons. *C. elegans* is the only animal in which amber suppressor mutations have been found, by using forward genetic analysis. Over 10 genes have been identified genetically as suppressors of amber (UAG) termination codons; most have been shown to encode $tRNA^{Trp}$ genes. Amber suppressor mutants are all at least semiviable, probably reflecting redundancy among the family of 12 $tRNA^{Trp}$ genes.

Several genes are known to be regulated at the level of mRNA translation. In all known cases, cis-acting sites in the 3′ UTR are required for proper regulation of translation. In the early (4-cell) embryo, the *glp-1* mRNA is ubiquitously expressed, yet is translated only in anterior blastomeres. During larval development, translation of the *lin-14* mRNA is downregulated by binding of the noncoding RNA *lin-4* to a repeated sequence in the *lin-14* 3′ UTR. The *lin-4* RNA is partly complementary to the *lin-14* repeats and forms duplex structures interrupted by bulges and loops. Formation of such hybrid structures prevents *lin-14* translation, by mechanisms that are still not well defined. The imperfect complementarity of *lin-4* and *lin-14* may be the reason why such dsRNAs are not subjected to degradation (RNA interference).

4.4 mRNA Surveillance and Nonsense-mediated Decay

All eukaryotic cells possess a system that degrades mRNAs with premature termination codons. This process, known as nonsense mediated decay (NMD) was identified in *C. elegans* by classical genetic analysis of a class of suppressor mutations known as *smg* mutations. Mutations in seven *smg* genes suppress the effects of premature stop codon alleles in a variety of genes. Such premature stop codons are distinguished from normal stop codons by their position relative to the last exon–exon junction, and subjected to rapid degradation. NMD may occur in the nucleus but is thought to happen mostly in the cytoplasm in concert with translation.

4.5 RNA Interference

RNA interference (RNAi) is a homology-based process by which endogenous mRNAs can be degraded by introduction of homologous double-stranded RNAs (dsRNAs). The importance of dsRNAs as triggers for RNAi was first revealed by work in *C. elegans*. Since its discovery in 1998, RNAi has become an essential part of the *C. elegans* repertoire of methods and has also yielded many unexpected insights into the mechanisms of gene expression and RNA metabolism. Double-stranded RNAs can be introduced into the animal by a variety of means: injection, soaking, feeding, or by transgenes; each method has its own advantages and disadvantages. Under optimal conditions RNAi can reliably

phenocopy the null phenotype of a gene; under nonoptimal conditions RNAi may be partly or completely ineffective in reducing gene function. Certain life stages appear to be more sensitive to RNAi than others. Some tissues, such as the nervous system, are refractory to RNAi; this limitation is being overcome by the use of mutant backgrounds that are more or less generally sensitized to RNAi. Nevertheless, at present, the sensitivity of any one gene to RNAi must be tested empirically and verified independently.

The general mechanism of RNAi is under intensive investigation in a variety of species and will not be summarized here. The *C. elegans* RNAi system is unusual in two key aspects. First, Bristol N2 *C. elegans* can ingest dsRNAs from its bacterial food (''feeding RNAi''). The mechanism of dsRNA uptake from food is not yet known. This highly convenient feature is polymorphic in *C. elegans*: the Hawaiian isolate CB4856 is sensitive to RNAi by injection, but not by feeding. It is not yet certain whether other nematode species, or other animals, are competent to take up dsRNA from food. Feeding RNAi, being highly scalable, has been critical in allowing genome-wide screens for gene function. Second, RNAi in *C. elegans* is often systemic: dsRNAs generated in one tissue (e.g. the intestine) can inhibit mRNAs in a different tissue (e.g. the germline), thereby implying the existence of a system for transferring dsRNA between cells. It is not known if all tissues are equally systemic, or whether certain tissues are more proficient in export or import of dsRNAs. Other animals, such as *Drosophila*, do not display systemic RNAi; the effects of RNAi in these animals are thus cell-autonomous. Genetic screens have begun to reveal the molecular requirements for systemic RNAi, which include the transporter-like protein SID-1.

One of the normal functions of the RNA interference mechanism is to provide a surveillance system that controls the level of transposition of endogenous transposons. The first clue to the normal role of RNAi came from the serendipitous discovery that mutants with elevated levels of transposition were also RNAi-defective. Double-stranded RNAs corresponding to transposon sequences could be generated by read-through of transposons from adjacent genes, in both sense and antisense directions. Some components of the RNAi mechanism have a dual function in the production of miRNAs such as *lin-4* and *let-7*, which are cleaved from precursor messages.

Keywords

Expressed Sequence Tags (ESTs)
cDNA clones that are derived from a cDNA library and partially sequenced to allow alignment with the genomic sequence.

Green Fluorescent Protein (GFP)
A naturally fluorescent protein in the jellyfish *Aequorea victoria*. Heterologous expression of the *gfp* gene is used extensively in many biological systems to address questions related to cell and molecular biology.

Microarray
A technique for analyzing simultaneous changes in expression of large numbers of genes that is based upon hybridization of fluorescently labelled mRNAs to DNA ''spots,'' each representing a gene, fixed to a solid support such as a glass slide.

MicroRNAs
Short single-stranded RNAs (~22 nucleotides) that are able to bind imprecisely to the 3′-untranslated regions of genes expressed during development, so mediating key temporal control of development.

Neuropeptides
Short peptides synthesized in nerve cells for use as neurotransmitters at synapses, or as neurohormones.

RNA Interference (RNAi)
The use of double-stranded RNA to elicit posttranscriptional gene silencing. RNAi was discovered using *C. elegans* and it is now widely utilized across the microbial, animal, and plant kingdoms.

Nematodes are ubiquitous roundworms. Many species are parasitic, causing immense economic damage to crops and livestock. Around a third of the world's population suffer from nematode infections.

The free-living *Caenorhabditis elegans* is a powerful model for the study of nematode biology, including animal development and behavior, as recognized by the award of the Noble Prize in Physiology or Medicine (2002) to Sydney Brenner, John Sulston, and Robert Horvitz, eminent biologists who pioneered this research field. *Caenorhabditis elegans* is amenable to classical genetic analysis, allowing large numbers of genes required for normal development and behavior to be identified by generating mutations. A scientific landmark was accomplished in 1998 with the publication of the entire genome of *C. elegans*, demonstrating that the complete

sequencing of the much larger human genetic code was technically feasible. The primary repository of all *C. elegans* physical and genetic data is Wormbase (www.wormbase.org). The draft genome of the closely related *C. briggsae* has recently been published, and efforts are ongoing to sequence the genome of the filarial parasite *Brugia malayi*. These genome sequences, together with numerous nematode expressed sequence tag (EST) projects from animal and plant parasites (www.nematode.net and www.nematodes.org), and the integrated physical and genetic map of the free-living marine nematode *Pristionchus pacificus*, will allow a more detailed understanding of the biology of the Nematoda. Such studies will present opportunities for the design of novel strategies for the control and therapy of parasitic nematodes.

1 Nematodes

1.1 The Nematoda and their Body Plan

Nematodes are probably the most ubiquitous phyla on earth. It is estimated that at least 40 000 species of nematode exist, of which about 20 000 have been described. Approximately 30% of described species are parasites of vertebrates, the remainder are either plant or invertebrate parasites, or free living. With one notable exception, *C. elegans*, parasitic species are the most heavily studied because of their economic and medical importance.

Nematodes are pseudocoelomic animals and their classification, historically, divided them into two groups, the Phasmidia (Secernentia), which are mainly marine, and the Aphasmidia (Adenophorea), which are predominantly terrestrial. With increasing genome sequence data becoming available, phylogenetic analyses segregate nematodes into five major clades and hence, the earlier classification of Phasmidia and Aphasmidia is now outdated. Parasitism appears to have evolved independently within each clade.

The typical nematode has a vermiform cylindrical body, tapered at both ends, with a pointed tail and blunt head (Fig. 1). The body wall is covered in a collagenous cuticle, comprised of scleroproteins, lipids, and carbohydrates. The cuticle may be smooth, or may bear a number of striations, ridges, or protuberances known as *alae* and *annular ridges*. Beneath the cuticle is a cellular, or syncytial hypodermis and a layer of longitudinal muscle cells. The muscle cells are uninucleated and each cell sends out at least one process towards a medial nerve. Nematode locomotion is constrained by the lack of circular muscles and by the rigidity of the cuticle. Many move in a sinusoidal manner, alternately contracting and relaxing opposed sections of the body. The nervous system is situated just below the hypodermis and consists of the nerve ring (brain) which encircles the pharynx, a complex head sensory system, and ventral and dorsal nerve cords that extend posterior from the nerve ring and run through almost the entire length of the body.

The alimentary system consists of a terminal mouth leading to a buccal cavity. The buccal cavity is lined with cuticle that can be specialized into plates, ridges, or, in

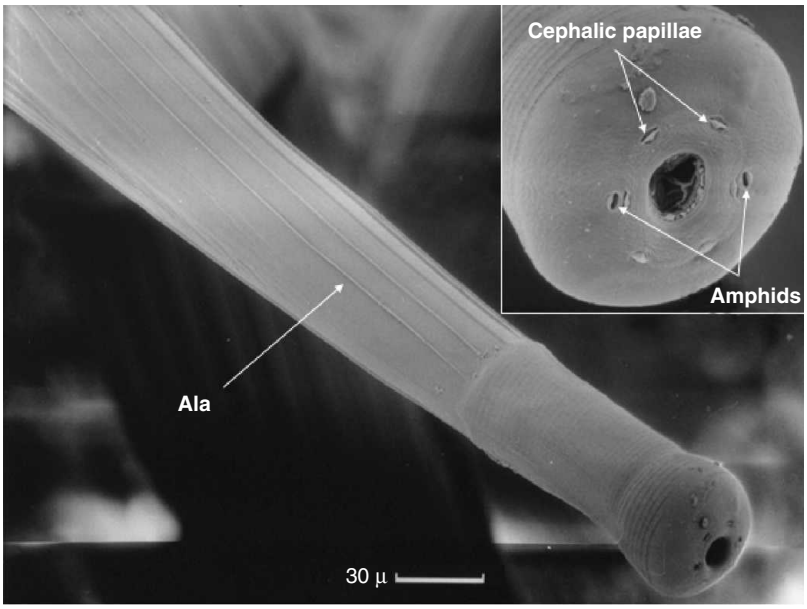

Fig. 1 Scanning electronmicrograph of an adult *Nematodirus battus*, a trichostrongyle intestinal parasite of ruminants. The image of the head (inset) shows the mouth surrounded by sensory organs.

the case of some carnivorous nematodes, teeth. The buccal cavity then leads into a muscular pharynx, an intestine, which is not lined with muscle, the rectum, and finally, a ventral subterminal anus. The gonads lie in the pseudocoelomic body cavity, which is bounded by the hypodermis and the intestine wall. The fluid filling the pseudocoelom provides a hydrostatic skeleton. Respiratory and circulatory organs are absent from nematodes.

The life cycle of parasitic nematodes may involve a free-living stage, or an intermediate host, as well as the primary host. The success of these nematodes is due to their ability to sense and to adapt to a new environment by changes in their structure, physiology, and behavior. Free-living nematodes also monitor and respond to changes in their surroundings, allowing them to survive shortages of food or other harsh environmental conditions. Sense organs are either chemosensory or mechanosensory and are found predominantly in the head region surrounding the mouth and in structures termed *amphids*, which are large paired chemosensory organs lying laterally on either side of the mouth. Other sense organs are found in lateral positions and those present in the posterior region of male nematodes are involved in the control of copulation. One group of nematodes also possess phasmids. These organs are also chemosensory and make contact with the external surroundings via pores on each side of the tail.

Nematodes follow a distinct developmental program: the embryo, four larval stages, and the adult organism. The cuticle is shed at the end of each larval stage. Many free-living and insect-parasitic nematodes also have a modified L3 larval

stage, termed the *dauer stage*, which is an adaptation to survive harsh conditions and hence, permit dispersal.

The majority of nematode species contain both sexes, but several, most notably, *C. elegans,* are hermaphroditic, with males arising only rarely.

1.2 The Model Organism *Caenorhabditis elegans*

Caenorhabditis elegans is a protandrous hermaphroditic nematode that inhabits soil and feeds mainly on bacteria. In the early 1960s, Sydney Brenner suggested that this organism be used as a model for metazoan development and, indeed, it has many features that make it ideal for the task. Its size allows it to be handled like a standard laboratory microorganism. The life cycle is relatively short (approximately 3.5 days at 20 °C) and the brood size large (>300). One sex of the species is hermaphroditic with two X chromosomes. Self-fertilization of the hermaphrodite allows individuals homozygous for recessive mutations to be generated from heterozygotes, a characteristic of immense value in genetic screens. The males of the species, with a single X chromosome, arise spontaneously in the population because of X chromosome nondisjunction, and they are vital in genetic experiments to permit combinations of different mutations. Interestingly, recent work has shown that some XX larvae generated by cross-fertilization lose one X chromosome when grown on specific metabolites. The same does not occur with XX larvae generated by self-fertilization, suggesting that sexual reproduction increases postembryonic developmental plasticity, allowing better adaptation of the species to environmental changes.

At all stages of its development, *C. elegans* is transparent, allowing continuous observation of individual cells. This advantage has led to a comprehensive map of all the developmental cell lineages in the animal. Moreover, since the cell lineage is almost entirely invariant in all animals, the properties of individual cells can be studied within the context of the whole developmental process. An individual cell can be ablated with a laser beam and the developmental mechanisms responsible for that cell's fate inferred from the consequences. Despite the invariance of the cell lineages, cell-to-cell communication appears to play a vital role in *C. elegans*' development. Interestingly, molecules implicated in cell–cell communication have been found to contain homology to conserved vertebrate signalling molecules.

Caenorhabditis elegans responds to starvation and to overcrowding by diverting second stage (L2) larvae to dauer larvae that are quiescent and resistant to harsh environmental conditions. In the presence of fresh bacteria, dauer larvae develop into fourth stage (L4) larvae and continue development to the normal adult stage. High levels of a *C. elegans* pheromone and low levels of an *Escherichia coli* food signal serve as two chemosensory cues to trigger the switch to dauer larvae. These signals are sensed by the amphids that comprise 12 sensory neurons, 8 of which end with nonmotile cilia that are in contact with the external environment via the amphidial pore.

1.3 Molecular Genetics and Postgenomic Biology of *C. elegans*

Classical forward genetic analysis of *C. elegans* is carried out by subjecting nematodes to a mutagen, such as ethyl methane

sulphonate (EMS), which induces random mutations in the germ line. Subsequent generations are screened for visible phenotypes. Using such approaches, Sydney Brenner and colleagues identified hundreds of mutants that included phenotypes showing movement and morphology defects. Genes, thereby defined through these mutations, are placed on a genetic map by performing genetic crosses and by analyzing the segregation of the phenotype with other known markers. Genes are molecularly cloned with reference to the physical map. Initially, cosmids are selected that span the desired genetic locus. The phenotype is then rescued by microinjection of the mutant with a series of overlapping cosmids. This should permit identification of a candidate gene and allow functional complementation to be carried out with a plasmid encoding the endogenous protein, hence proving unambiguously the genotype–phenotype relationship. Forward genetic approaches have defined about 10% of the predicted *C. elegans* genes, and when combined with emerging technologies, elucidation of the biological role of the remaining genes may be possible.

With the completion of the *C. elegans* genome sequence, techniques were developed to isolate mutants carrying mutations in desired genes – an approach termed *reverse genetics*. Chemical mutagenesis (EMS) is used to generate banks of mutants that are subsequently screened by the polymerase chain reaction (PCR) to detect a deletion in the gene of interest. The *C. elegans* gene knockout consortiums (http://celeganskoconsortium.omrf.org and http://shigen.lab.nig.ac.jp/c.elegans) are utilizing such methodology to isolate mutants for all predicted genes. Alternatively, the genome of *C. elegans* contains a number of endogenous *Tc* transposons that integrate randomly in the genome. These *Tc* transposons have been used to generate libraries of mutants that contain a transposon insertion in any given gene. PCR screens are again employed to isolate a mutant in a specific gene.

Forward and reverse genetic approaches are time consuming and the initial method of choice to analyze gene function in *C. elegans* is now RNA interference (RNAi). The double-stranded RNA (dsRNA) can be introduced by microinjection, overnight soaking, or by feeding nematodes on RNAse-deficient bacteria induced to express the dsRNA from a T7 promoter-based plasmid. The latter two approaches are amenable to genome-scale analyses. The ability of dsRNA to spread throughout the worm body, known as *systemic RNAi*, requires the presence of the transmembrane protein SID-1. Neuronal expressed genes appear less susceptible to RNAi, although, mutants are now available with increased sensitivity to dsRNA. RNA interference has transformed gene analysis and allowed genome-wide screens to be carried out by feeding and soaking. This RNAi-generated phenome dataset reveals functions for 14% of the genome, with the most common phenotype being embryonic lethality. Evolutionary conserved genes are more likely to result in a RNAi phenotype than genes that have evolved more recently. RNAi appears to be ubiquitous and hence, unsurprisingly, it is now reported effective as a gene silencing mechanism in both animal and plant parasitic nematodes. Although RNAi is extremely powerful, a thorough description of the biological function of a gene and its genetic pathway will still necessitate further analyses using a gene knockout mutant and enhancer and/or suppressor screens.

The metazoan developmental program requires precise coordination of the temporal and tissue-specific expression of large numbers of genes to correctly generate the morphological structures of the body. Unusually, for a eukaryote, *C. elegans* has a high proportion of genes that are found in operons and, hence, are transcribed polycistronically. Unlike prokaryotic operons, genes found within *C. elegans* operons are generally not functionally related. *Caenorhabditis elegans* is ideally suited for analyses of the spatio/temporal control of gene expression since germ-line transformation with promoter–reporter gene constructs is relatively easy. Furthermore, because *C. elegans* is transparent throughout development and the entire cell lineage has been determined, reporter gene activity can be studied precisely in all developmental stages. Our laboratory (IAH) is currently involved in analyzing large numbers of these expression patterns (http://bgypc086.leeds.ac.uk).

Gene expression patterns are generated by fusion of the genomic region immediately upstream of a gene (promoter) to a reporter gene (*lac*Z or *gfp*). The *lac*Z gene encodes the enzyme β-galactosidase, and its sites of expression are readily visualized with a histochemical stain that produces a blue precipitate wherever gene product is generated. The major advantage of using a *gfp* reporter gene is that expression patterns can be visualized in living animals. A significant proportion of such transgenes fail to drive reporter gene expression, which may reflect a higher proportion of pseudogenes present within the genome than initially envisaged. Analyses of the expression patterns of homologous *C. elegans* and *C. briggsae* promoters in both species show that the upstream regulatory elements are well conserved. Interesting differences do however exist; the *lin-48* gene of *C. elegans*, but not *C. briggsae*, is expressed in the excretory duct cell and this difference correlates with the more posterior position of the excretory pore in *C. elegans*. Promoters from several parasitic nematodes have been shown to drive reporter gene expression in *C. elegans* in a manner that shows good spatial agreement, though not so good temporal regulation, with the *C. elegans* homolog. This may reflect an increased rate of evolution upon the temporal element of nematode promoter sequences.

A large library (~190 000) of expressed sequence tags has been generated for *C. elegans*. A significant proportion of these ESTs show no homology to sequences deposited in databases. A thorough understanding of the biology of *C. elegans*, or any other organism, will require elucidation of the biological roles that these novel proteins, identified from EST databases, play. *In situ* hybridization studies, also using EST sequences, have determined approximately 7000 mRNA expression patterns for *C. elegans* genes (http://nematode.lab.nig.ac.jp).

Many open reading frames have been amplified from cDNAs and cloned using bacteriophage λ-based recombination technology (Gateway™ cloning). The resulting library of ORFeomes permits subsequent ease of manipulation into plasmids specialized for addressing different biological questions. This technology has also been used to clone PCR-amplified cDNAs for about 70% of predicted genes for which there is no EST evidence, generating a set of ORF sequence tags (OSTs). This dataset has raised the total number of experimentally confirmed genes in *C. elegans* to ~17 500 and indicated that computer predictions for gene splicing are ~70% accurate.

Global changes in gene expression, analyzed using microarray technology, have provided a *C. elegans* gene expression map that clusters genes with well-coordinated expression throughout development (http://cmgm.stanford.edu/~kimlab). A recent refinement has shown that it is possible to analyze gene expression using microarray technology in specific cells by selectively expressing **green fluorescent protein** (GFP) in the desired cells and, then, culturing these cells following extraction from the embryo with fluorescence activated cell-sorting (FACS). The identification of genes involved in pharyngeal organogenesis combined microarray, bioinformatic, and molecular genetic approaches and demonstrated that a forkhead box A transcription factor regulated this gene network.

The developmental profiling of protein expression is required to fully understand the complexity of biological processes since many events are mediated by post-translational protein modifications and, hence, not detectable by global gene expression analyses. To this end, technical improvements in two-dimensional protein gel analysis and identification by mass spectrometry (proteomics) have allowed *C. elegans*' stage-specific and temperature-regulated proteins to be identified.

Protein-interaction maps, utilizing yeast two-hybrid technology, are also being constructed as a means of understanding the proteome in the context of specific biological processes. The combination of interactome and phenome (RNAi) approaches is extremely powerful and has allowed identification of candidates involved in the response to DNA damage, including the orthologue of a gene frequently mutated in chronic lymphocytic leukemia. Other protein–protein interactions have been studied for vulval development, the germ line, and the proteasome (http://vidal.dfci.harvard.edu) and in total, the interactome map for *C. elegans* currently contains about 5500 interactions.

A complete understanding of molecular interactions requires knowledge of the three-dimensional structures of the interacting proteins. To this end, a *C. elegans* structural genomics initiative is underway, with the aim of expressing and purifying all predicted proteins and then producing high quality crystals suitable for X-ray diffraction (http://sgce.cbse.uab.edu).

2 Nematode Neurobiology

2.1 Anatomy of the Nematode Nervous System

Many nematode researchers study nematode neurobiology in order to understand more complex neural systems and their emergent behaviors. Other researchers are interested in the design of antinematode drugs, and the nervous system has been the focus for many of these studies. Almost all that is known about the neurobiology of nematodes comes from work done on *C. elegans* and *Ascaris suum*, an intestinal parasite of pigs. As the nervous systems of *C. elegans* and *A. suum* are well conserved, it is likely that the results of these studies can readily be extrapolated to many other nematodes.

The nervous system of *C. elegans* has been described completely at the cellular level and contains 118 classes of neuron comprising sensory neurons, motor neurons, and interneurons (http://www.wormatlas.org). The adult hermaphrodite contains 302 neurons and

56 supporting cells (socket and glial-like sheath cells). Owing to differences in the number of sex-specific neurons required for mating, the adult male contains 381 neurons and 92 supporting cells. Electron micrographs were used to determine the position and connectivity of every neuron within the animal and the resulting ''wiring diagram'' reveals that *C. elegans* contains about 5000 chemical synapses, 600 gap junctions, and 2000 neuromuscular junctions. The neuronal pattern is constant from animal to animal and individual neurons have been assigned functions following their removal by laser ablation.

Most neuronal cell bodies are in the head region, surrounding the pharynx, which itself contains 20 neurons that are physically separated from the rest of the nervous system by a basement membrane. The remaining cell bodies are in the ventral, lateral, or posterior regions of the tail. A single process (axon) usually emanates from the cell body, and synaptic contact can be formed with multiple adjacent processes (dendrites). The presynaptic region thickens and appears electron dense by electron microscopy, indicative of the accumulation of synaptic vesicles. Dendrites receive multiple synaptic inputs, though the lack of electron-dense material, indicative of a postsynaptic region in other organisms, hinders assignment. The pharynx is surrounded circumferentially by the nerve ring, the brain of the worm, which contains most of the interneurons, and synaptic connections. The nerve ring receives and transmits information via processes within the dorsal, ventral, and two lateral nerve cords that extend along the entire length of the body. The nerve cords are interconnected by commissures. Neurons of the head region are organized into an anterior ganglion and five ganglia that are posterior to the nerve ring. The tail region contains a preanal ganglion and four ganglia that are posterior to the anus.

Many of the sensory neurons project processes to the amphids in the nose tip, giving direct access to the environment and allowing chemosensation. A single amphid neuron is able to respond to multiple chemicals, suggesting that multiple receptors exist. Individual chemosensory neurons appear to sense distinct chemicals, with some overlap. Other chemosensory neurons project into the pseudocoelomic fluid. All chemosensory cells are surrounded by a sheath cell whose secretions are vital for chemoreception. Temperature is monitored by a thermosensory amphid neuron, allowing detection of very small temperature changes (0.05 °C). The thermosensory neuron has an enlarged membranous area, perhaps indicating that thermal changes may be detected via changes in membrane fluidity. Six touch-sensory neurons are present in the head and tail region, with processes embedded within the hypodermis to allow fine response to mechanosensation. Touch cells have specialized microtubules with 15 protofilaments, as opposed to the usual 11 protofilaments, which possibly confers greater rigidity toward mechanical stresses.

The motor neurons innervate body-wall, pharyngeal, egg-laying, and defecation muscles. In addition, the male has further motor neurons that control mating behavior; contact, turning, vulva location, spicule insertion, and sperm transfer. These behaviors require the activity of ray sensory neurons, hook and postcloacal sensilla, and spicule sensory neurons. Body-wall and defecation neuromuscular junctions are unique since the muscle cells project neuronal-like processes, termed *muscle arms*, to the motor neuron and synapses are made on the muscle arm.

The body-wall muscles receive synaptic input from excitatory and inhibitory motor neurons of the ventral and dorsal nerve cords, allowing out-of-phase contractions and, hence, sinusoidal movement.

Electrophysiological analyses of individual neurons allows assignment of the physiochemical properties of a nerve cell relative to time and activity and, hence, assesses the contribution any one cell can make to the neuronal circuit and animal behavior. Most work has been carried out with the porcine parasite, *A. suum*, since it can grow to 30 cm in length, aiding dissection of nervous tissues and the visualization of identified neurons for patch-clamp recordings. The large number of *C. elegans* behavioral mutants is an important resource for electrophysiology studies, however, the small size of this model nematode has hindered progress. Most work has been carried out with neuromuscular junctions of the pharynx and a small number of sensory and locomotory neurons. Recent advances with primary culture techniques for *C. elegans* neurons and muscle cells and the use of fluorescent indicators of membrane potential and calcium dynamics should ensure that exciting progress is made in this area.

2.2 Nematode Neurotransmission

Completion of the *C. elegans* genome-sequencing project has revealed that the basic machinery of neurotransmission exhibits much similarity with mammals, though genes associated with gap junctions and chemosensory receptors appear to have evolved independently. There are numerous types of potassium channels and several calcium and chloride channels, but no voltage gated sodium channels. Remarkably, about 5% of *C. elegans* genes encode G protein-coupled receptors. Most of these are designated as orphan receptors since the ligands, and hence functions, are unknown, though many are likely to be chemosensory receptors.

The major neurotransmitter of excitatory motor neurons is acetylcholine, while GABA (γ-aminobutyric acid) is the main neurotransmitter of inhibitory motorneurons. Acetylcholine results in cation channels becoming permeable and a number of antinematode drugs target the cholinergic system of nematodes. Organophosphorous anticholinesterases prevent inactivation of acetylcholine, while the imidazothiazoles, such as levamisole, activate nicotinic acetylcholine receptors at nerve–muscle junctions. Muscle cells also possess a muscarinic-like acetylcholine receptor, explaining why nicotinic receptors are not essential for the survival of *C. elegans*. γ-Aminobutyric acid stimulates opening of Cl^- channels, and in *C. elegans*, the GABAergic system is associated with three distinct behaviors. Most GABA neurons are involved in regulating the waves of contraction that run along the worm's body during locomotion. In response to cholinergic excitatory neurons causing muscle contraction, the GABAergic neurons inhibit muscle contractions on the opposite side of the body, initiating the characteristic sinusoidal pattern of movement. Animals with defects in these neurons have dorsal and ventral contractions occurring simultaneously, causing the animal to shrink. Other GABAergic neurons are involved in limiting the motion of the head during foraging. In contrast with the inhibitory function of other GABAergic neurons, two excitatory GABAergic neurons stimulate the final, expulsive step of defecation.

Glutamate is required for pharyngeal pumping and more recently, it has been

associated with long-term memory in *C. elegans*. Glutamate activates a Cl^- channel that is sensitive to ivermectins, a class of extremely potent drugs that reduce motor activity in nematodes. *Caenorhabditis elegans* also contains AMPA and NMDA receptor classes that respond to glutamate.

Biogenic amines found in nematodes include dopamine and serotonin, which have been localized to small subsets of neurons. Serotonin is found in the hermaphrodite-specific neurons (HSN), which control egg laying in *C. elegans*, and is present in two neurosecretory cells in the pharynx of *C. elegans* and *A. suum*. Serotonin has also been implicated in the regulation of locomotion and carbohydrate metabolism in *A. suum*, and the coordination of male copulatory behavior in free-living nematodes.

Dopamine appears to be the major catecholamine present in many nematode species, inhibiting locomotion and egg laying in *C. elegans*. Octopamine antagonizes the effect of serotonin and causes defects in movement and reduction in egg laying, pharyngeal pumping, and defecation. Noradrenalin has been identified in some species of nematode, but appears to be absent in *C. elegans*.

Immunocytochemistry has revealed peptidergic neurons in the pharyngeal nerves and the nerve cords, and a family of neuropeptides with Arg-Phe-NH_2 at the C-terminus have been isolated from *A. suum*, *C. elegans*, and *Panagrellus redivivus*. More than 60% of *A. suum* neurons are immunoreactive for Phe-Met-Arg-Phe-NH_2-related peptides (FaRPs), and a number of FaRPs have been shown to have potent effects on the inhibitory motorneurons of *A. suum*. *Caenorhabditis elegans* genome predictions indicate that 92 genes encode neuropeptides. This rich diversity includes 23 *flp* genes that encode multiple (~60) FaRPs, 37 insulin-related genes, and 32 *nlp* (neuropeptide-like protein) genes. Mutation of the *flp-1* gene causes defects in locomotion, mechanosensation, chemosensation, and egg laying.

2.3 Behavioral Mutants of *C. elegans*

The cell lineage and connectivity of all 302 neurons present in *C. elegans* hermaphrodites have been described in detail. This information, coupled with the powerful genetics and the availability of large numbers of behavioral mutants affecting locomotion, sensory input, survival, and reproduction has made *C. elegans* an excellent model for studying the genetic pathways that determine the development and functioning of the nervous system. Such studies have made major contributions to the understanding of nervous systems of nematodes and higher organisms; examples being the identification of the first GABA transporter (*unc-47*), the first glutamate transporter (*eat-4*), the first odorant receptor (*odr-10*), and the first member of the netrin family of axon-guidance molecules (*unc-6*).

Survival encompasses such behaviors as foraging, feeding, defecation, and dauer larva formation. Feeding is achieved through pharyngeal muscle contractions, allowing a grinder in the terminal bulb of the pharynx to break up bacteria before entry into the intestine. Laser ablation has shown that three neurons are essential for pharyngeal pumping, and by taking recordings from dissected pharyngeal muscles (electropharyngeograms), the M3 motor neurons were shown to inhibit pumping by controlling the time of muscle relaxation in response to the neurotransmitter glutamate. The *eat-4* mutant shows delayed

pharyngeal relaxation due to a reduction in the release of glutamate into neuronal terminals.

Many egg-laying defective mutants have been described, some of which fail to synthesize serotonin in the HSN (hermaphrodite-specific neurons) cells, while other mutants have abnormalities in HSN morphology and migration. Detailed studies of egg-laying defective mutants have led to the elucidation of the genetic pathway for the development of the HSN cells and includes the identification of genes that control HSN migration, axonal outgrowth, and the biosynthesis of serotonin.

Mutations (dauer-constitutive or *daf-c* and dauer-defective or *daf-d*) that affect the induction of dauer larvae by pheromone stimulation have led to the construction of a genetic pathway controlling dauer formation. Temperature-sensitive *daf-c* mutants enter the dauer stage even under favorable growing conditions. In contrast, *daf-d* mutants block dauer formation under strong dauer-inducing conditions. Most of the *daf-d* genes are required for normal sensory cilia structure in the amphid sensillia. Laser ablation experiments have identified two amphid neurons that repress dauer formation in the absence of pheromone and which are derepressed in the presence of pheromone. Characterization of the protein products encoded by *daf* genes has provided molecular and biochemical understanding of the signal transduction pathway for dauer formation. For example, d*af-1* and *daf-4* genes encode cell-surface receptors belonging to the serine/threonine protein kinase family, and the DAF-4 receptor has been shown to bind members of the bone morphogenetic protein family.

Caenorhabditis elegans NPR-1 is a receptor for FaRP neuropeptides encoded by the *flp-18* and *flp-21* genes and is structurally related to the neuropeptide Y receptor family. A single amino acid change in NPR-1 determines whether the animal exhibits solitary (Val215) or social (Phe215) feeding behavior. Nematodes carrying an *npr-1* gene deletion are social feeders, indicating that *npr-1* functions to suppress social feeding. Social feeding is induced by stressful conditions (e.g. overcrowding) activating mechano- and chemosensory nociceptive neurons, resulting in the opening of a cation channel. Social feeding is also induced by activation of a cyclic GMP-gated ion channel present in three neurons that contact the pseudocoelomic fluid. The activation of NPR-1 in these neurons again leads to suppression of social feeding behavior. The interplay between the two neuronal systems, therefore, results in complex regulation of the feeding behavior of *C. elegans*.

The complex mating behavior exhibited by *C. elegans* males is also being genetically dissected. Many mutants have been isolated that affect male development and, hence, the capacity to copulate. The desire to copulate is determined by the presence of hermaphrodites and physiological indicators of nutritional and reproductive status, including serotonin. Mutation of the serotonin reuptake transporter, *mod-5*, which functions to remove serotonin from the synaptic cleft, reduces mate searching. Interestingly, inhibitors of the human serotonin reuptake transporter (e.g. the antidepressant Prozac) also decrease libido, indicating that it may be possible to understand certain mammalian motivational behaviors using worm genetics.

2.4 *Caenorhabditis elegans* as a Neurodegenerative Disease Model

Since the *C. elegans* nervous system contains the basic neuronal machinery and its genome encodes homologs of human neuronal disease genes, it is studied as a model system for neurodegenerative diseases. Dissecting genetic pathways involved in neuronal disease in *C. elegans* may offer new insights into the roles of crucial gene products and may possibly lead to novel strategies for neuroprotection in humans. Transgenic nematodes that model neurodegeneration might also be screened against chemical banks in the search for novel pharmaceutical compounds that may alleviate the disease symptoms.

Caenorhabditis elegans has a single gene, *apl-1*, that is homologous to human amyloid precursor protein. The nematode gene lacks the neurotoxic β-amyloid peptide fragment, and hence, modeling Alzheimer's disease has involved intracellular expression of human β-amyloid in *C. elegans*. Studies have shown that the endoplasmic reticulum heat shock protein, HSP70, is protective against β-amyloid plaque formation in this transgenic model. Presenilins are components of the γ-secretase complex that cleave the amyloid precursor protein and release β-amyloid. The *C. elegans* presenilin homolgue, *sel-12*, cleaves members of the Notch transmembrane receptor family, and genetic screens have identified candidate components of the γ-secretase complex. Large-scale presenilin inhibitor screens are underway to induce egg-laying defective *C. elegans* that phenocopy the *sel-12* mutant and, hence, provide lead compounds to combat Alzheimer's disease.

Polyglutamine (polyQ) disorders, such as Huntington's disease, are characterized by expansion within exons of the CAG triplet, resulting in intracellular protein aggregation and neurodegeneration. The N-terminal polyQ fragment of human huntingtin protein has been expressed in *C. elegans*. A genetic screen for enhancers of neurodysfunction identified *pqe-1* as a candidate for neuroprotection, most likely through the prevention of cellular proteins becoming aggregated with polyQ proteins.

Caenorhabditis elegans is also being exploited as a model of other neurodegenerative diseases, including disorders such as Parkinson's disease, mucolipidosis (*cup-5*), and necrotic-like neuronal cell death (*mec-4*).

3 Development in *C. elegans*

3.1 Normal Development

Caenorhabditis elegans is the only metazoan for which a developmental program has been described completely at the cellular level. A collection of time-lapse movies showing various stages of *C. elegans* development can be accessed via http://www.bio.unc.edu/faculty/goldstein/lab/movies.html. The embryonic development of *C. elegans* takes place over 14 h at 20 °C and occurs in two distinct stages. Following fertilization in the *spermatheca*, the oocyte completes meiotic division, the gamete pronuclei are fused, the egg shell is formed, and mitotic cell division is initiated. A period of rapid cell division then occurs to generate a 550-cell ovoid with little overt differentiation. It is during this period that the eggs are generally laid, though during adverse conditions (e.g. starvation), the hermaphrodite can retain eggs in the uterus. The second stage

consists of differentiation and morphogenesis with little additional cell division. If the eggs are still inside the uterus due to adverse conditions, the embryos will continue to develop and hatch, resulting in the characteristic "bag-of-worms" phenotype.

Caenorhabditis elegans has a largely invariant cell lineage. The initial unequal cell divisions generate six founder cells, AB, C, D, E, MS, and P_4. These founder cells give rise to cell lineages that divide synchronously and equally (daughter cells of equal size) with characteristic division rates. Some founder cells produce a single tissue; E gives rise to all of and only the intestine, whereas other founder cells produce many different tissue types.

Gastrulation starts 100 min after first cleavage when the embryo consists of 28 cells. The two daughter cells of the founder E move from the ventral surface to the embryo interior where they will form the intestine. The MS descendants, which form part of the pharynx and the myoderm, and the germ-line progenitor, P_4, follow the E lineage through the ventral cleft. Gastrulation is complete after cells of the D lineage and the descendants of C, which generate the body-wall muscle, complete their movements. Movement of neuroblast cells within the ectoderm, mediated by ephrin signalling events, ensures that the ventral cleft closes after 230 to 290 min of development. Epidermal cells are born about 240 min after the first cleavage, and epidermal enclosure of the embryo, a process termed *epiboly*, is initiated. The dorsal epidermal cells intercalate (290–340 min) and ventral epidermal enclosure becomes complete (310–360 min). Epidermal enclosure is mediated by ephrins, α- and β-catenins, cadherins, and semaphorins.

Morphogenesis occurs due to contractions of the circumferentially orientated actin microfilament bundles within the epidermis, causing cells to change shape and the embryo to increase in length, approximately fourfold (about 360–600 min). Muscle and nerve cells start to differentiate and the embryo begins to twitch. After elongation is complete, the hypodermis secretes the cuticle (about 650 min), ensuring that the characteristic shape of the worm is maintained.

Postembryonic growth results in an approximate fourfold increase in length, with the cuticle being shed at the end of each larval stage. Two members of an unusually large family of nuclear hormone receptors (*nhr-23* and *nhr-25*) and a novel member of the angiotensin-converting enzyme family that lacks a metallopeptidase active site (*acn-1*) are essential for these moults (Fig. 2). During larval development, 32 blast cells continue to divide and the number of somatic nuclei increases from 558 to 959 in the hermaphrodite and from 560 to 1031 in the male. The final cell divisions to occur are those of the lateral hypodermis (seam cells) during the L4 larval stage. The somatic cells generated postembryonically contribute mainly to the sexually dimorphic structures such as the gonads, the vulva of the hermaphrodite, and the male tail. The postembryonic cell lineage and migrations have been completely described.

3.2 Manipulation of Development

Individual cells in a developing animal can be destroyed by a tightly focused microlaser beam and the effect on development ascertained. Such experiments support the interpretation made from the invariant cell lineages that *C. elegans* development was

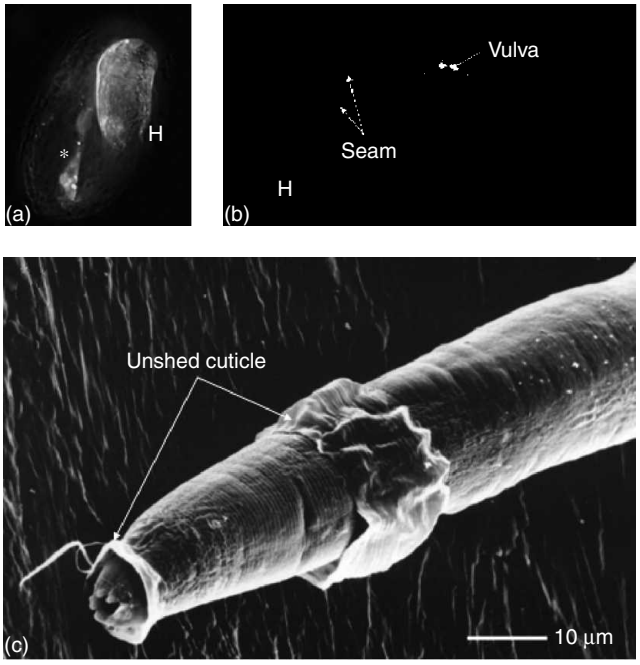

Fig. 2 Developmental expression and RNAi phenotype of *C. elegans acn-1*, a novel member of the angiotensin-converting enzyme family. Fluorescent images of transgenic *C. elegans (H; head)* expressing *acn-1::gfp* show reporter gene activity in (a) the lateral hypodermal seam cells (individual seam cell is highlighted with an asterisk) of a late-stage embryo and (b) in the seam and vulva cells of an L4 hermaphrodite. (c) Scanning electronmicrograph showing the head region of an adult *C. elegans* that has failed to shed cuticle during larval moults because of *acn-1 (RNAi)*.

largely cell autonomous; remaining cells failed to compensate for the structures that would have derived from the destroyed cell(s). For example, ablation of muscle precursors from the C or D lineages leads to larvae with gaps in the longitudinal bands of muscle.

However, there are several examples of nonautonomous development. In the developing gonad, the cells Z1.ppp and Z4.aaa are a cell pair for which the primary fate is to be an anchor cell and the secondary fate is to be a ventral uterine precursor cell. If either cell in this pair is destroyed by laser ablation, the remaining cell always adopts the primary fate. This suggests that the two cells are in ''competition'' for the primary fate, with the ''loser'' adopting the secondary fate. These two cells have equivalent developmental potential and are said to belong to an ''equivalence group''. Further laser ablation experiments have revealed other equivalence groups of postembryonic development that do not show natural variation during normal *C. elegans* development. During vulva development, Wnt and EGF signalling events distinguish the fate of the six cells of the ventral epidermis, which

form an equivalence group, known as the *vulva precursor cells*. The anchor cell of the gonad then provides the primary inductive signal (EGF-like protein LIN-3) for vulva formation by directing P6.p to adopt the primary fate, generating eight great-grandprogeny that form the center of the vulva (vulF and vulE cells). The flanking vulva precursor cells, P5.p and P7.p, adopt the secondary fate, forming seven progeny (vulA, B1, B2, C, and D cells). This is ensured as a consequence of P6.p lateral signalling, via the LIN-12 receptor, inhibiting P5.p and P7.p and hence, preventing these from adopting the primary fate. An inhibitory signal from the hypodermal syncytium, hyp-7, directs the two daughters of P3.p, P4.p and P8.p to adopt the tertiary fate and fuse with the hypodermis.

Early embryonic development also depends on many inductive interactions and AB.a and AB.p cells, that generate about two thirds of all embryonic cells, have equivalent developmental potential. Signaling from P_2 to AB.p is responsible for specifying the cell fates of the AB.p lineage.

Many genes involved in the cell lineages of *C. elegans* have been identified by mutations that affect the development of particular structures such as the vulva. One of the better characterized developmental mutations in *C. elegans* affects *lin-12*. This gene is best understood for its role in cell fate decision of the gonadal cells, Z1.ppp and Z4.aaa, as discussed above. Genetic analysis of *lin-12* mutants showed that the *lin-12* gene product specified the ventral uterine precursor cell fate of Z1.ppp or Z4.aaa. This analysis further suggested that *lin*-12 function is part of a receiving mechanism for a signal sent out by the presumptive anchor cell that enables expression of the secondary fate. The *lin-12* gene was isolated and found to encode a transmembrane protein with a sequence similarity to the Notch protein, which is involved in cell fate decisions in *Drosophila*.

Heterochronic genes coordinate the temporal sequence of events during development. Mutations in the heterochronic genes cause precocious or retarded development of specific cell lineages. Mutants in *lin-4, lin-14, lin-28, lin-29, lin-41,* and *lin-57* (*hbl-1*) have allowed the heterochronic gene pathway controlling the larval to adult switch to be characterized. The *lin-4* gene is expressed during L1 stage and it encodes a 22 nucleotide noncoding RNA, known as a *microRNA*, which represses *lin-14* and *lin-28* by imprecise base-pairing to their respective mRNAs. A second microRNA, *let-7*, is expressed during the L3 stage and it represses *lin-41* and *lin-57* (*hbl-1*). It is likely that many more microRNAs will be characterized with key functions during development. For example, the microRNA *lys-6* has recently been shown to control neuronal patterning by repression of *cog-1* during left/right axis formation in chemosensory neurons.

3.3 Nervous System Development

The AB cell lineage generates nearly all the neuronal cells of *C. elegans* (291 out of 302) and most (222) are formed during embryogenesis. A further 72 develop during the first larval stage and the final eight hermaphrodite neurons form during the L2 stage. Male-specific neurons continue to develop during the L3 larval stage. Neurons of the same cell type arise from different neuroblast sublineages that are reiterated. Most neuronal cells are born into their approximate final position and pioneer axonal processes emerge. The growth cone, present on

the tip of the axon, is able to detect and interpret guidance cues (netrins, slit, ephrins, and semaphorins) secreted from the ectodermal cells through modifications to its cytoskeleton. There are numerous axon pathfinding mutants, many of which map to transcription factors that are likely to regulate localized expression of the guidance molecules. A growth cone-independent mechanism also appears to operate in the migration of the proximal trajectory of the M2 motorneuron through the muscle cells of the pharynx. This unusual occurrence may be a consequence of pharyngeal development, which occurs via morphogenesis of a primordium of undifferentiated cells and without cell divisions. The pioneer axons guide subsequent axonal processes to their destinations. Nerve cell development is complete following onset of neurotransmitter expression. Most postembryonic ventral motor neurons express acetylcholine or GABA shortly after axonal migration. In contrast, expression of FMRF-related peptides in the VC cells, which arise during the first larval stage, does not occur until late in the L4 stage.

The nervous system of *C. elegans* exhibits plasticity during development. During embryogenesis, the GABAergic DD motor neurons innervate the ventral muscles and then, at late L1 stage, these rewire, losing connections with the ventral muscles and forming synapses with the dorsal muscles. During dauer formation, synaptic remodeling of some of the amphid chemosensory neurons also occurs. Some of the neurons develop larger processes, while the sensory endings of others retract within the amphidial pore. Neuromuscular changes occur during development of the adult male. For example, GABA release from the AVL and DVB neurons causes contraction of the enteric sphincter muscle in the L4 male and relaxation of it in the adult male.

3.4 Cell Fusion

Cell fusion is critical to *C. elegans* embryonic and postembryonic development and in the adult hermaphrodite, 300 of the 959 somatic cell nuclei are present within large multinucleate cells known as *syncytia*. During embryo elongation, cell fusion occurs between most of the dorsal cells and a number of the ventral cells to form the hypodermal syncytia. During each larval stage, the lateral hypodermal cells (seam cells) divide and one daughter cell remains in the seam, while the other daughter cell migrates and fuses with the hypodermal syncytia. Additional ventral epidermal cells also fuse with the hypodermal syncytia during larval development, with the net result being that the hypodermis of the adult comprises of eight syncytia (186 nuclei) and only three unfused cells. The seam cells also fuse during the L4-adult moult to generate the two lateral hypodermal syncytia of adults. The overall effect of all these cell fusions is to generate a tissue, and importantly, to also restrict the migratory paths of the remaining nonfusing cells.

Cell fusion events are also critical during development of the vulva. Cell fusions that occur during the L1 and L3 larval stages serve to affect cell fate determination of the ventral epidermal cells and vulva precursor cells. During the early L4 larval stage, cell fusions occur between migrating vulva primordial cells (precursors of the vulA and vulC cells). At the late L4 stage, intratoroidal cell fusions occur between the sister cells of the remaining five multicellular stacks to form a syncytial ring. In the final stage, the gonadal anchor

cell penetrates the vulva apex and fuses with the uterus.

Additional cell fusions occur during development of the pharynx, the excretory glands, and also the male tail. Genetic screens have identified EFF-1 as a key player in embryonic and postembryonic epithelial cell fusions. EFF-1 is an ectodomain protein attached to the cell surface by a single transmembrane domain. The functional basis of EFF-1 in cell fusion is probably related to the presence of a 22–amino acid putative fusion peptide sequence and/or a consensus phospholipase A2 active site within the large ectodomain.

3.5 Programmed Cell Death

During normal development of an adult *C. elegans* hermaphrodite, 131 out of 1090 somatic nuclei and large numbers of germ cells die by programmed cell death. During his Nobel Prize studies on the invariant cell lineage, John Sulston reported that most of the somatic programmed cell deaths occur during embryogenesis (113/135). A small number of programmed cell deaths also occur during the L2 stage of hermaphrodite development and in the male larval stages. Most programmed cell deaths involve neuronal and neuron-associated cells and hypodermal cells. A few muscle cells and sisters of the pharyngeal gland cells also undergo programmed cell deaths. For instance, the HSN neurons, required for egg laying, are destroyed by programmed cell death in males. Likewise, the CEM neurons, the male sensory neurons used in mating, undergo programmed cell death in hermaphrodites shortly after they arise.

Programmed cell death follows a characteristic pathway that is evolutionarily conserved. It involves a change in cell morphology, disintegration of the nucleus, and finally, engulfment of the dead cell by its healthy neighbors. Genetic analysis of *C. elegans* cell death mutants, pioneered by the Nobel Prize studies of Robert Horvitz, has identified a number of genes implicated in programmed cell death, with *ced-3* and *ced-4* being the most central. Normal developmental cell death is abolished in mutants lacking either of these genes, resulting in them having 12% more cells and a nervous system about one third larger than wild-type *C. elegans*. The *ced-3* gene encodes a cysteine protease from the caspase family, while CED-4 has homology to the mammalian apoptotic protease-activating factor, Apaf-1.

The activity of the gene *ced*-9 appears to be crucial in preventing cell death in inappropriate cells. The CED-9 protein is localized to the mitochondrial membrane and it shows sequence homology and functional similarity to the protein product of the human proto-oncogene *bcl-2*. Programmed cell death is suppressed when CED-9 binds CED-4, whereas cell death is initiated when CED-9 interacts with EGL-1, a BH3-domain-only member of the *bcl-2* family. The latter interaction releases CED-4, allowing it to activate the caspase CED-3, the key executioner of programmed cell death.

A recent genetic screen has also identified the *icd-1* gene as a suppressor of programmed cell death. ICD-1 is the β-subunit of the nascent polypeptide-associated complex and its expression suppresses cell death by a *ced-4* mediated, *ced-3* independent pathway, demonstrating that the core programmed cell death machinery can have distinct roles. This study also raises the possibility that other caspase family members may have crucial roles during programmed cell death.

3.6 Aging

There is huge divergence in life spans of species within Nematoda, with many free-living nematodes existing for weeks, whereas parasitic species can live for years (e.g. the filarid *Loa loa* may live up to 20 years). This disparity in longevity is a consequence of genetic differences that have evolved to reflect species ecology. Significant life-span differences can also be found within the same species of nematode and this is, in part, likely to reflect environmental variations. One particularly important factor for an ectothermic organism, such as a nematode, is temperature. For example, the *C. elegans* hermaphrodite has a maximum life span of 32 days at 16 °C and this decreases to 11 days at 25.5 °C. Another major influence is the availability of food, with significant life-span increases observed through dietary restriction. Recent laser ablation studies using *C. elegans* have led to the identification of specific gustatory and olfactory neurons that influence longevity. *C. elegans* mutants have been isolated with altered life span, and the dissection of genetic pathways of aging has begun. The *daf-2*/insulin receptor pathway is central to longevity; decreased signalling increases life span up to threefold. The *daf-2* mutant phenotype is suppressed by the forkhead transcription factor *daf-16*. Combining transcriptome and genome-wide RNAi analyses in *daf-2* and *daf-16* mutant backgrounds has identified target genes that modulate *C. elegans*' life span. Additional genetic screens have shown that *C. elegans*' mitochondrial proteins, including components of the energy generating electron transport chain, regulate longevity in a *daf-16* independent manner. One unifying hypothesis is that mutants with enhanced life spans use an anaerobic fermentative mitochondrial metabolic pathway, shown to operate in dauers, that results in a significant reduction in damaging free-radical oxygen species.

Acknowledgment

We wish to thank Darryl MacGregor for his contribution, Adrian Hick, Mike Winter, and Donald Lee (School of Biology, University of Leeds) for permission to use the electromicrograph in Fig. 1, Gareth Howell (Wellcome Trust Bioimaging Facility, University of Leeds) for assistance with Fig. 2.

Keywords

Biomarkers
A biological marker, or biomarker, is a phenotypic parameter (e.g. a substance, structure, or process) that is measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention. In cancer research and detection, a biomarker refers to a substance or process that is indicative of the presence of cancer in the body. It might be either a molecule secreted by a malignancy itself, or it can be a specific response of the body to the presence of cancer.

Cluster Analysis
A technique for grouping a collection of objects into subsets or clusters such that those within each cluster are more closely related to one another than are objects assigned to different clusters.

DNA Hypermethylation
An increased level of DNA methylation in a DNA sample at either an individual CpG dinucleotide or a group of dinucleotides relative to a reference DNA sample, usually derived from a normal tissue.

Early Detection
Detection of the disease (cancer) before it metastasizes and there are options of preventing it.

Epigenetics
Epigenetics is the study of processes that establish metastable (i.e. somatically heritable) states of gene expression without altering the DNA sequence. In large part, the field of epigenetics addresses processes that affect *DNA methylation* and/or *chromatin structure* to establish such metastable, but somatically heritable, states of

gene expression. Thus, epigenetic phenomena can be defined as changes in the genetic material (specifically the genomic DNA and chromatin) that alter the regulation of gene expression in a manner that is somatically heritable (and sometimes heritable through the germline) but that is nonmutational, that is, does not involve changes in the DNA sequence.

Mass Spectrometry
A field that, in its biological applications, uses sophisticated analytical devices to determine the precise molecular weights (mass) of proteins and nucleic acids, as well as the amino acid sequence of protein molecules.

Proteomics
The characterization and quantification of proteins and protein systems. Proteomics methods allow for the comparison of patterns of proteins isolated from bodily fluids or cells, in normal versus diseased subjects.

SELDI-TOF
Surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF**)** is a method for profiling a population of proteins in a sample according to the size and net electrical charge of the individual proteins. The position of an individual protein in the spectrum produced corresponds to its ''time of flight'' because the small proteins fly faster and the large proteins fly more slowly.

Sensitivity and Specificity
Sensitivity is the true-positive test results (individuals with disease who test positive for that disease) expressed as a percentage of all tested individuals who have that disease (total of true positives and false negatives). When applied to cancer, sensitivity is the chance that a person with cancer has a positive test. (http://www.nci.nih.gov/cancerinfo/pdq/screening/overview). In the context of biomarker testing, the *clinical sensitivity* of a biomarker refers to the proportion of case subjects (individuals with confirmed disease) who test positive for the biomarker assay, *Analytical Sensitivity* refers to the sensitivity of an assay that is used to detect a biomarker of disease, that is, the ability of the assay to detect a biomarker given that it is present. *Clinical Sensitivity* is a composite of the biomarker prevalence in a tumor, the efficiency of transfer of the marker to the bodily fluid or tissue being tested, and the analytical sensitivity of the assay.
Specificity is the true-negative results (tested individuals without disease who test negative for that disease) expressed as a percentage of all tested individuals who do not have that disease (total of true negatives and false positives). When applied to cancer, specificity is the chance that a person without cancer has a negative test (http://www.nci.nih.gov/cancerinfo/pdq/screening/overview). In the context of biomarker testing, *specificity* refers to the proportion of control subjects (individuals without disease) who test negative for the biomarker assay.

Cancer development involves several stages: initiation, development, and progression. Biomarkers can be used to detect cancer in different stages. The desirable property and utility of a biomarker lies in its ability to provide an early indication of disease progression. Biomarkers should be easy to detect; measurable across populations; and suitable for detection at an early stage, identification of high-risk individuals, early detection of recurrence, and as an intermediate endpoint in chemoprevention. Recent technological advances have helped develop noninvasive, sensitive, and specific biomarkers in small clinical samples to detect preneoplasia.

1 Introduction: Current Status in Diagnostics for Early Cancer Detection

Cancer is a heterogeneous disease in most respects, including its cellularity, different genetic alterations, and diverse clinical behaviors. Alterations in gene sequence, expression levels, and protein structure and function have been associated with every type of cancer. These changes can be used to detect cancer, determine prognosis, and monitor disease progression and therapeutic response. One of the major challenges is to identify these molecular changes and incorporate the information into the clinical setting. Perhaps a major challenge in cancer medicine is to recognize the ''black sheep of the family''; that is, those tumors in the family that are clinically distinct but blend in by histology. In breast cancer, for example, infiltrating breast carcinoma appears homogeneous histologically but heterogeneous clinically (at least five distinct tumor subtypes were identified by biomarker and gene expression profiling).

Several cancers originate in the epithelium that lines the internal surfaces of organs throughout the body. Although these are readily treatable provided they are diagnosed in preinvasive stages, early lesions often evade detection before they become invasive. Specifically, the nuclei become enlarged (from 5–10 μm to 20 μm), crowed and hyperchromatic, as detected by histological examination. However, light-scattering microscopy now offers a biopsy-free means to measure the size distribution and chromatin content of epithelial cell nuclei as an indicator of preinvasive neoplasia.

Detection of mutator phenotype may provide a snapshot of subsequent changes. Normal mutation rates are insufficient to account for the multiple mutations found in different cancers. Cancers must exhibit a mutator phenotype early during evolution. The mutator phenotype

hypothesis was originally postulated for mutations in genes involved in DNA replication (especially fidelity in DNA replication) and DNA repair. Currently, other genes that affect chromosome segregation, damage surveillance (e.g. checkpoint control) and cellular response (e.g. apoptosis) are also included. The mutator phenotype arising from mutations in genetic stability genes can have diverse manifestations, such as point mutations, microsatellite instability, and loss of heterozygosity.

During the long time interval associated with cancer development, cancer cells acquire the capacity to divide, invade, and metastasize. According to mutator hypothesis, these phenotypes result from mutations in genes that maintain gene stability in normal cells. Thus, mutations in several genes (and whole genome) will be affected because of mutations in the genetic stability genes. Some of the resulting mutations will exhibit selective advantages, allowing the mutated cells to expand and achieve clonal dominance.

It has been proposed that genetic instability in human cancers can be divided into two categories; microsatellite instability, which is usually equated with DNA polymerase errors, and chromosomal instability, which can result from errors in chromosome partitioning. In the case of endometrial and colorectal cancers, most tumors exhibit either chromosomal instability or microsatellite instability, but not both. It is emphasized here that chromosomal instability and microsatellite instability are well characterized as a result of facile detection by current methods, PCR and karyotyping, respectively. Conversely, detection of random mutations, particularly point mutations, is more difficult, and this has limited the search for evidence of a mutator phenotype at the single nucleotide level.

It remains to be determined whether the acquisition of a mutator phenotype underlies tumor progression and when the enhancement in mutation rate occurs during the life of tumors. In order for a mutator phenotype to be necessary for tumor progression, it would have to occur early and result in the accumulation of large numbers of random mutations; the existence of multiple mutations in cancer cells has important implications in stratification, tumor evolution, and treatment. A functional classification of cancer markers is presented in Table 1.

The application of biomarkers in clinical practice has been limited to single entity quantitation and to small panels of tests that identify changes in proteins, the presence or absence of which signifies an important event. The ongoing discovery of new biomarkers lends to the belief that no single marker will provide sufficient information for detection and diagnosis. Therefore, a multiparameter, multimarker approach to biomarker development and validation is needed. Efforts should be made to take advantage of the number of tumor samples now available in tissue banks to identify new molecular markers and to assess existing ones more fully. A list of biomarkers for cancer diagnosis is presented in Table 2.

2 Examples of Diagnostic Markers for Preneoplasia

Two major classes of genes – oncogenes and suppressor genes – are involved in carcinogenesis. Oncogenes are activated or deactivated genes whose products normally promote cell growth. Products

Tab. 1 Functional classification of cancer diagnostic markers.

Function	***Marker***	***Tumor type***
Angiogenesis	Thrombospondin-1 (TSP-1), TIMP-3	Several
Apoptosis		
Cell cycle	p15, p16, p73, DAP kinase	Acute myeloid, lymphoid leukemias, lymphomas, lung
DNA repair	BRCA1, glutathione S-transferase, hMLH1, LKB1, methylguanine methyl transferase (MGMT)	Breast, colon, gastric, endometrial
Invasive/metastasis suppressor	CD-44, E-cadherin, TIMP-3	Brain, colon, renal
Oncogenes		
Tumor antigen	Thrombospondin-1 (TSP-1), TIMP-3	Several
Tumor suppressor	APC, AR, ARF/INK4A, HIC1, p15, p16, p73, p53, RARβ, Rb, VHL	Several

include peptide growth factors, growth factor receptors, signal transduction factors, tyrosine kinase, and transcription regulatory proteins. Several oncogenes have been mapped within the human karyotype. Tumor suppressor genes normally regulate cell growth. These genes typically produce nuclear regulatory proteins, which interact with other regulatory proteins to alter their activity. The frequent involvement of a limited number of oncogenes, for example, *c-myc* and *ras*, in a wide variety of tumor scenarios suggests, nevertheless, that the number of the most critical genes needed for the transformation process may be limited. This suggests that we might be able to develop common approaches to detect these cancers.

Genes not related to the oncogenes or suppressor genes have been implicated in carcinogenesis. These advances have fueled optimism that abnormal genes, whether acquired or inherited, may be used to assess the risk of cancer or to detect existing cancer early even in its preclinical stages. Knowledge of the biology of tumor progression, therefore, allows us to identify specific tests useful for early detection or screening. Molecular probes, for instance, could detect altered DNA shed into the feces (colorectal cancer), into the sputum (lung cancer), and in exfoliated cells in bladder washings (bladder cancer). Correlation of the molecular alterations with demographic data, risk factors, environmental exposure, family history, and dietary history may provide important information on the etiology of cancer.

Molecular genetic alterations could also contribute toward the assessment of risk. Risk assessment is the search for risk factors that provide the earliest evidence for the risk of cancer in persons not diagnosed with the disease. Biomarkers that are predictive of risk usually trigger more aggressive interventions and surveillance. The earliest risk factors are probably inherited genetic defects, which are well demonstrated in the case of colorectal cancer. Adenomatous polyposis coli (*APC*) and hereditary nonpolyposis colorectal cancer (HNPCC) are associated with germline mutations in the *APC* gene and mismatch repair genes, respectively. Large bowel cancers often arising at a young age are found

Tab. 2 Tumor types and biomarkers. This is a partial list of biomarkers that are abnormally regulated in preneoplasia and have the potential to be used in cancer diagnostics.

Tumor type	*Gene*
Bone	Cathepsin, urokinase plasminogen activator
Breast	BRCA1, BS106, BU101, CDH1, Cyclin D1, DAPK, GSTP1, Her-2/neu, p16, mammaglobin, TIMP-3
Brain	MGMT, p16, $p14^{ARF}$, TIMP-3
Bladder	APC, DAPK, p16
Cervical	GSTP1, FHIT, MGMT, p16, RARbeta
Colon	APC, BAT-26, Beta catenin, DAPK, DCC, galactin-3, hMLH1, K-ras, L-DNA, MGMT, MCC, p16, $p14^{ARF}$, TIMP-3
Esophagus	APC, CDH1, GSTP1, $p14^{ARF}$, p16
Glioma	MGMT
Head and neck	DAPK, MGMT, p16, PAI-2
Kidney	APC, CDH1, DAPK1, GSTP1, MGMT, p16, $p14^{ARF}$, TIMP-3
Leukemia	CALC1, CDH1, DAPK1, MGMT, p15, p73
Liver	AFP, APC, complement-3 fragment, DCP, GP73, GSTP1, p16
Lymphoma	DAPK, MGMT, p16, p15, p73
Lung	Annexin I and II, CyP-A, DAPK, E-cadherin, GSTP1, FHIT, MIF, MGMT, p16, $p14^{ARF}$, p38, RARbeta, RASSF1A, TIMP-3
Oral	DCC, CADH1
Ovary	Alpha heptaglobin, BRCA1, CA125, DAPK, kallikrein-6, LPA, MMP, osteopontin, prostasin, p16
Pancreas	APC, CDKN2A, GSTP1, MGMT, p16
Prostate	B23, GSTP1, kallikrein-2, PSA, PSMA, p27
Stomach	APC, DAPK, HMLH1, MGMT, p16
Uterus	hMLH1, p16, $p14^{ARF}$

Note: AFP: alpha fetoprotein; APC: adenomatous polyposis coli; CALC1: calcitonin; CDH1: E-cathedrin; CyP-A: cyclophilin A; DAPK: death-associated protein kinase; DCC: deleted in colon cancer; DCP: des-gamma carboxy-prothrombin; FHIT: fragile histidine triad; GP73: glycoprotein 73; GSTP1: glutathione S-transferase P1; HMLH1: human mut L homolog; L-DNA: long DNA; LPA: lipophosphotidic acid; MCC: mutated in colorectal cancer; MGMT: O6-methylguanine-DNA methyltransferase; MIF: macrophage migration inhibitory factor; MMP: metalloproteinase; PAI-2: plasminogen activator inhibitor-2; PSA: prostate-specific antigen; PSMA: prostate-specific membrane antigen; RARbeta: retinoic acid receptor beta; RASSF1A: RAS association domain family protein 1A.

in almost 100% of individuals who inherit *APC* gene mutations.

Few diagnostic markers are available currently. Examples of such markers include prostate-specific antigen (PSA) for prostate cancer and serum carcinoma embryonic antigen (CEA) for colorectal cancer. About one-third of patients with an elevated PSA level undergo further unnecessary medical procedures, however, because they do not have a malignant form of prostate cancer. New molecular markers are needed that can identify patients who are at high risk for developing life-threatening cancers and patients who harbor aggressive tumors that require immediate treatment. A comprehensive list of biomarkers with potential in cancer diagnostics is presented in Table 2.

In colon cancer, for example, delineation of various stages during tumor progression offers a window of opportunity

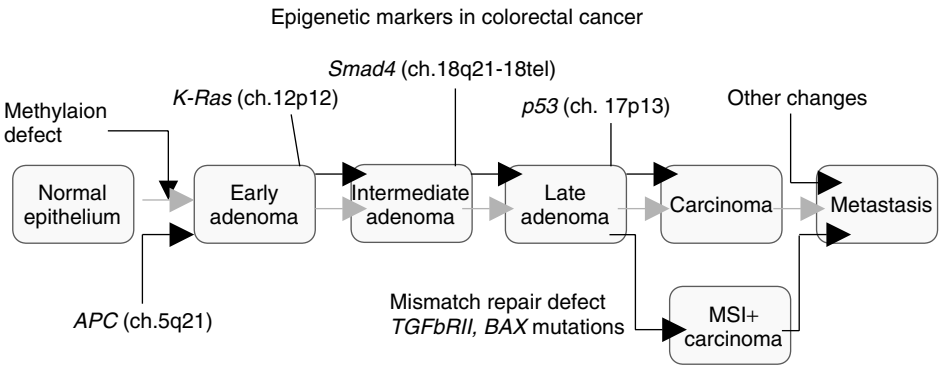

Fig. 1 Epigenetic markers in colon cancer. A general model of colorectal cancer is presented. A number of epigenetic markers express during early stages of the cancer development. These markers can be used for cancer diagnostics. Since epigenetic changes are reversible, these markers could be the potential therapeutic targets also.

to intervene in the process by detecting stage-specific molecular changes (such as changes in gene expression and accumulation of mutations) (Fig. 1). To date we know of mutations and loss of heterozygosity (LOH) which affect oncogenes such as *K-ras*, and several tumor suppressor genes including *p53*, *MCC* (mutated in colorectal cancer), *APC*, and *DCC* (deleted in colon cancer).

3 Application of Biomarkers in Cancer Detection

DNA released from cells that regularly slough into the stool can be used to identify cancer or precancerous polyps in the colon. A multi-target DNA assay panel (*MTAP*) was developed, which shows a remarkably higher sensitivity and specificity than traditional fecal blood tests. The *MTAP* targets point mutations at any of 15 mutational hot spots on *K-ras, p53*, and *APC* genes; Bat-26, a microsatellite instability marker and L-DNA have been identified. Using this test a sensitivity of 91% and a specificity of 100% were observed. Thus, an assay of altered DNA from exfoliated cells holds promise as a stool-screening approach for colorectal neoplasia.

Recently, Campa et al. identified two differentially expressed proteins, macrophage migration inhibitory factor (MIF) and cyclophilin A (CyP-A), in lung cancer specimens using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry(MALDI-TOF MS). Cyp-A is a member of the immunophilin family of proteins, typically studied for their binding of various immunosuppressive drugs, most notably cyclosporine A, and their role in cellular signaling pathways. This is the first demonstration of the utilization of MALDI-TOF MS in screening lung fingerprints and identifying novel markers.

Because of the multifactorial nature of cancer, it is very likely that a combination of several markers will be necessary to effectively detect and diagnose cancer. To look for such ''fingerprints'' of cancer, it will require not only high-throughput genomic or proteomic profiling but also sophisticated bioinformatics

tools for complex data analysis and pattern recognition. Taking advantage of the recent development in surface-enhanced laser deionization/ionization (SELDI) and of the ProteinChip technology, Petricoin's group was able to simultaneously analyze the protein profiles of 169 serum samples from patients with or without breast cancer. The software package ProPeak allows evaluation of each mass peak according to its collective contribution toward the maximal separation of cancer patients from the noncancer controls. These two advances led to the identification of three discriminatory biomarkers that, in combination, achieved both high sensitivity (93%) and high specificity (91%) in detecting breast cancer patients from the noncancer controls. Using the same technology, Petricoin's group has identified differentially expressed protein profiles specific for early stages of ovarian and prostate cancer with very high sensitivity and specificity.

3.1 Case for Early Detection

The Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute (NCI) is an authoritative source of information on cancer incidence and survival in the United States (www.seer.cancer.gov). The SEER program currently collects and publishes cancer incidence and survival data from 11 population-based cancer registries and three supplemental registries covering approximately 14% of the US population. The SEER registries routinely collect data on patient demographics, primary tumor site, morphology, stage at diagnosis, first course of treatment, and follow-up for vital status. The information collected in the program above is very useful in biomarker discovery and validation.

The Gail Model, developed at the NCI, is a statistical tool to help estimate a woman's risk of breast cancer based on a number of predisposing factors. A study of the reliability of mammographic densities was completed recently, and this characteristic has been found to be reliable enough to be formally included in the model.

3.1.1 Detection Leads to Better Surveillance

We have described below, as an example, that the ovarian cancer patients with *BRCA* mutations have better survival than noncarriers. Women who inherit mutations to the *BRCA1* or *BRCA2* gene have a greater risk of developing ovarian cancer. However, until recently, researchers could not predict whether women with these mutations would fare better, the same, or worse than other women with ovarian cancer. This issue was examined via the medical records of almost 900 newly diagnosed ovarian cancer patients with inherited *BRCA* mutations and their progress was followed for five years. On average, the patients with *BRCA* mutations survived about 20 months longer than women without the mutations. This survival advantage was not due to earlier detection, but seems to reflect a difference in the pattern of disease in women with and without *BRCA* mutations. The mechanism of this phenomenon is not known. Further follow-up in this study should reveal whether the longer survival of *BRCA* mutation carriers is a long-term phenomenon or is limited to the first few years of the disease. Thus, *BRCA* mutation has been used as a useful biomarker in ovarian cancer studies.

In a separate multicenter study, mutations in the ataxia telangiectasia (ATM) gene was used to screen a large population for breast cancer. Ataxia telangiectasia is an autosomal recessive disorder

characterized by a progressive cerebellar ataxia, occulo-cutaneous telangiectasias, immune deficiency, chromosomal instability, hypersensitivity to ionizing radiation, and an increased incidence of cancer. ATM shares significant sequence similarity with a family of large serine–threonine kinases that play a crucial role in cell-cycle regulation. ATM functions as a protein kinase, phosphorylating a large and growing list of substrates, including BRCA1, in response to the presence of DNA double-stranded breaks. Although ATM carriers do not display any specific phenotype, they had a significant increased risk of death due to breast cancer. Generally, ATM carriers are more sensitive to the lethal effects of the ionization radiations. To investigate the relationship between breast cancer, radiation exposure, and genetic variation in the ATM gene, the WECARE (Women's Environment, Cancer and Radiation Epidemiology) study was conducted where multiple centers (2100 subjects) participated. Results indicated novel mutations, detected by denaturing high-pressure liquid chromatography (DHPLC), in the ATM gene identified both in patients with antaxia telangiectasia and in patients with unilateral or bilateral breast cancer. These results point to the importance of screening techniques with the sensitivity to detect both missense and truncating mutations. In addition, the importance of standardizing the lab conditions cannot be minimized in a multicenter study of this nature, and in the type of quality control assessments described in this study, which will reduce bias and laboratory errors.

3.1.2 Early Detection Leads to Improved Survival

An analysis of temporal trends for esophageal cancer patients diagnosed in 1961–1996 in Sweden showed improvement in relative survival rates (RSRs), but data were not available on stage at diagnosis or on cancer-directed treatment. In another study, the temporal changes in RSRs by histology for esophageal cancer patients in the United States were reported. In the NCI's SEER program, data were obtained from nine locations. Patients with esophageal cancer as the first or only reportable cancer were identified, excluding those ascertained only by death certificate or autopsy. Using a computer program that includes mortality rates for the general US population (by age, sex, and race), RSRs at 1, 3, and 5 years after diagnosis in 1975–1979, 1980–1984, 1985–1989, 1990–1994, and 1995–1998 were obtained for squamous cell carcinoma and adenocarcinoma of the esophagus (defined by ICD-O-2 morphology codes). Confidence limits on RSRs were estimated as $\pm$ twice the SE ($p = 0.05$). RSRs increased over time for both squamous cell and adenocarcinoma, beginning earlier than in Sweden. The overall increases from 1975–1979 to 1995–1998 were similar for the two histologic groups, but the larger sample sizes for squamous cell carcinoma in the earlier years resulted in statistical significance for more comparisons than for adenocarcinoma. Age-standardized incidence rates for adenocarcinoma of the esophagus in the SEER program have surpassed the declining rates for squamous cell carcinoma. For squamous cell carcinoma patients, RSRs were statistically, significantly higher in 1980–1984 versus 1975–1979 and in 1985–1989 versus 1980–1984 (except for the 5-year RSR); thereafter, increases were smaller. RSRs were slightly higher for adenocarcinoma than for squamous cell carcinoma, but differences were not statistically significant.

Another example in this area is that of pancreatic cancer. It is known that about 10% of all cancers of pancreatic cancer are hereditary. However, although mutations have been found in the tumors of patients with nonhereditary pancreatic cancers, the major genes responsible for inherited cases are yet to be discovered. Investigators searched for suspicious mutations in the *BRCA2* gene of pancreatic patients who had at least three relatives with this disease. They discovered mutations likely to be involved in tumor development in 17% of patients in this study. Further research is needed to define the risk of pancreatic cancer in patients with these mutations better. Additional genetic as well as environmental factors may influence this risk.

More information is needed on a variety of topics relevant to cancer diagnostic biomarkers. Identification of risk factors and potential confounders for different markers is another. Both sources and extent of variability (intra and interindividual), which can have both genetic and environmental sources, and laboratory variability, which has both random and systematic components, are important. Understanding the natural history of biomarkers, analogous to the natural history of disease, will help us to use biomarkers effectively in epidemiological studies.

4
Technology Advancement in Diagnostics

The last 20 years have seen a molecular revolution influencing all aspects of oncology: from the *in vitro* modeling of genetic and epigenetic mechanisms of oncogenesis and tumor propagation to *in vivo* animal models of malignancy and from the clinical stratification of patients following ''biomarkers'' to the actual targeting of molecular defects using drugs specifically designed for that purpose. The transgression of novel findings in the field of molecular oncology can take virtually years from bench to bedside. *BRCA1* and *BRCA2*, for example, were discovered in the early eighties but their clinical implication could only be achieved several years later.

In the past few years, a number of technologies and assays have emerged that can be used for cancer detection. In the following section, we have discussed those techniques that are being used or have the potential to be used in a clinical set up for early cancer detection and risk assessment. The major categories of these technologies are genomics, epigenomics, proteomics, gene expression profiling (RNA-based techniques), and imaging.

Two major categories in the technology advancement in diagnosis are:

1. Patterns Analysis as a Marker
2. Target Specific Detection.

4.1
Pattern Analysis as a Marker

Techniques to identify alterations in protein structure or function that are associated with cancer include antibody-based detection methods, measurement of enzymatic activity, two-dimensional gel analysis (2DGE), and surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI TOF MS). By combining features of systemic and local disease markers into reference standards for the diagnosis of new disease entities, functional proteomics has the potential to redefine illness. A brief description of selected proteomic techniques and their

implications for the molecular diagnosis of cancer is given in the following section.

4.1.1 Surface-enhanced Laser Desorption/Ionization Mass Spectrometry (SELDI)

Implication of affinity MS to the identification and measurement of cancer-associated biomarkers was achieved by Ciphergen Biosystems, Inc. (Fremont, CA) to develop SELDI ProteinChip® MS technology. In protein analysis, SELDI has several advantages over other existing technologies such as liquid chromatography-MS (LC-MS), 2-D gel electrophoresis coupled-MS (2DGE-MS), enzyme-linked immunosorbent assay ELISA, and fluorescent-based binding assays for high-throughput screening because of its versatility, ease of use, speed, and cost. SELDI-MS is rapid, reproducible, highly sensitive (i.e. its detection limit is in the femtomolar range), and it is readily adaptable to a diagnostic format. Its major limitations are the difficulty in identifying proteins detected in mass spectra and the limited ability to detect most proteins in complex samples. SELDI-TOF-MS has been utilized for discovering proteomic patterns in blood and offers a novel approach for early cancer detection. Proteomic signatures emanate from the cell as cancer develops, and the emanating proteins generate biomarker profiles that end up in the effluent blood surrounding the cells. The concept is that the collection of proteins flowing into the tissue can be modified as it leaves the tissue because of enzymatic events from the cancer cell or the host, or proteins could be added to the perfusing blood as biomarkers. The serum proteome is a complex of thousands of proteins and peptides and the smaller posttranslationally modified proteins that are cleaved, glycosylated, phosphorylated, or tagged with a lipid, provide a wealth of diagnostic information about the pathologic state of this tissue.

In a SELDI pattern, the cancer diagnostic proteins are identified without knowing their function. One challenge of this technology is to identify the proteins derived in the cancer cell from those derived from the host cell. This is a low-resolution system that can process one drop of raw serum on a microchip that binds proteins. A profile of differentially expressed proteins is generated. After validating the protein patterns, an algorithm is developed to find the subset of proteins that are diagnostic of the cancer compared to the noncancer state. The genetic algorithm takes two sets of training data and finds the subset pattern that can detect the difference between the two training populations. That pattern is mapped in *n*-dimensional space as a series of clusters and an unknown sample can thus be compared to the cluster to determine if it is a cancer or normal pattern.

SELDI analysis of serum from prostate, ovarian, and bladder cancer patients and a comparison with normal serum identified distinct disease-specific protein profiling. Results have been encouraging for identifying cancer in men with PSA levels between 4 and 10 mg ml^{-1}, which is a level that has no specificity for that test. The use of the multiparametric proteomic patterns application method was able to identify men who subsequently developed prostate cancer. Results of investigations for ovarian cancer showed that the algorithm could identify patterns that were subsequently found to be cancerous. The specificity and sensitivity were very high in these studies.

The hope is that if cancer researchers can shift the diagnosis of ovarian cancer from stage III, where it currently exists, to stage I, many lives will be saved. Moving to a clinical testing situation will demand a more advanced and reliable system than

is now available. Therefore, current efforts are being made to move from the SELDI-TOF-MS to the QSTAR technology, which can offer much higher resolution, quicker response times, and assessment of a wider molecular weight range of proteins. In preliminary tests with the QSTAR, results have been very encouraging.

4.1.2 Two-dimensional Gel Electrophoresis

Two-dimensional (2-D) gel electrophoresis is the most widely used tool for separating proteins in expression proteomics. In 2-D gel electrophoresis, proteins are separated first in one dimension on the basis of isoelectric point and then in a second dimension on the basis of molecular mass. In some cases, 2-D gel electrophoresis may evaluate whole cell or tissue protein extracts. The pH gradient employed in the first dimension can also vary, depending on the application. Using very narrow, immobilized pH gradients for the first-dimension separation increases resolving power and can help detect low-abundance proteins. Radioactive or fluorescent labeling or silver staining offers visualization of hundreds of proteins. Differences between the samples can be compared and relative quantities determined by quantifying the ratios of spot intensities in independent 2-D gels. MALDI-TOF mass spectrometry (MS) allows the analysis and identification of very small amounts of protein isolated from the gel. These advances have combined to make 2-D electrophoresis a more attractive option for the analysis of complex protein mixtures.

4.1.3 Immunoassays

Immunoassays are the fastest-growing technologies for the analysis of biomolecules and are used widely for diagnostic purposes. The development of a competitive binding assay using radioisotopes and enzyme-labeled probes later was a major milestone in antibody-based immunoassays. These developments paved the way for an enormous expansion in application of these technologies, particularly in biomedical research and in clinical chemistry. These assays are limited, however, to the analysis of a few thousand assays per day, even with the adaptation of the microtiter plate format. Furthermore, the presence of only known analytes that can be screened for becomes a serious bias in proteome analysis, where unknown gene products are significant. A new technology, gene and protein microarrays, is further advancing the ability to perform tens of thousands of assays in parallel. The first analytical breakthrough came with the use of oligonucleotides and cDNA microarrays; however, the analysis of the proteome requires a different approach and the development of protein microarrays using protein chips.

4.1.4 Protein Arrays

Protein arrays are composed of multiple recombinant proteins that are arranged in an orderly fashion on a small surface. The protein and antibody arrays are mostly miniaturized immunoassays for multiple proteins and antibodies, respectively. They also can be used to detect protein–protein, protein–ligand, protein–DNA, and protein–RNA interactions, however. Their production could be automated using either pin-based or liquid microdispenser robots. Protein and antibody microarrays will be the approach of choice to close the information gap between genomics and proteomics in the development of new markers for the early detection, diagnosis, and classification of cancer. Ordered microarrays of proteins, protein ligands, or antibodies directed at well-defined

antigens are the best platform for the high-throughput, precise analysis of quantitative differences between the proteomic maps of healthy and cancer-stricken individuals. This emerging technology will be applied to identify differences at the cellular level, to compare normal cells and cancer cells from the same organ, and to compare body fluids such as plasma and urine from healthy donors and cancer patients. Advantages of this assay are its reproducibility, scalability, and quantitation.

4.1.5 Mass Spectrometry

Direct qualitative and quantitative comparisons of complex protein mixtures have been greatly facilitated by the development of a high-throughput mass spectrometry (MS). This method employs a chemical group or label made in two isotopic forms: heavy and light. These labels, isotope-coded affinity tags, combine with all of the cysteine residues in a protein mixture. The heavy reagent is added to one sample and the light reagent is added to another sample. These samples are combined, and the resulting protein digestion and peptides are analyzed via MS. The isotopic substitutions do not affect the behavior of the peptides during separation. Thus, peptides derived from the two different samples enter the spectrometer at the same time. The MS measures the relative abundance of heavy and light peptide forms in each sample and identifies each peptide by generating and analyzing the peptide fingerprints. In this manner, a global view of the protein abundance in cells or tissues in two different states of health emerges.

4.1.6 Matrix-assisted Laser Desorption/Ionization (MALDI)-time-of-flight (TOF) Mass Spectrometry (MS)

Matrix-assisted laser desorption/ionization (MALDI)-time-of-flight (MALDI-TOF) uses a nitrogen laser. MALDI-TOF samples are irradiated after coating the sample with an energy-absorbing matrix. Molecules from the surface are dissolved and accelerated, and their TOF is measured to determine molecular weight, mass, and electrical charge.

Liquid chromatograph (LC)–tandem mass spectrometer (TMS), which is an tandem mass spectrometer (MS-MS) instrument combined with LC to measure molecular species disassociated from a matrix, is utilized in determination of sequences of peptides.

MALDI-TOF and LC-TMS technologies are applied to develop images from protein samples. There are several advantages of the MALDI technologies: they are a very high-throughput discovery tool, can perform direct analysis of tissues, have high-molecular specificity, can be used for simple protocols, and result in multiple images at different molecular weights. These technologies can be used for protein identification and in the study of PTMs. The highest sensitivity is in the molecular weight range below 50 kDa. Although it currently is possible to analyze proteins up to molecular weight 30 KDa, there is a decline in accuracy and specificity above 50 kDa. There is a requirement of further processing for protein identification. Images developed from these methods can illustrate the distribution of a specific molecular weight molecule (i.e. protein) in a tissue slice. The range of molecular weights using these methods is between 1000 and 100 000 m/z. The MALDI-TOF results are very reproducible. The profiles produced by these methods may be used to follow the progression of a disease, but not to classify the disease. These methods can identify protein patterns to be used as biomarkers or can be used to determine the efficacy of drug therapy with biopsy

material. A finding that may be applicable to both areas is that different proteins exist in different regions of a tumor.

Another improved technology, MALDI-QSTAR (QqTOF) is used to determine concentration of drugs in tissue. The QSTAR is a quadrapole TOF MS-MS machine and can be very specific for very low concentrations of a protein. This technology can help show the positive correlation between LC-MS analysis, which can take days to analyze, and MALDI imaging, which can be completed within minutes, in drug analysis studies.

4.1.7 Laser Capture Microdissection

The most tedious job in proteomics is sample preparation, as some proteins are insoluble in a heterogeneous mixture of cells. An important advance in sample preparation is the development of l**aser capture microdissection(**LCM). Although manual microdissection can achieve good precision, it is time consuming, labor intensive, and requires a high degree of manual dexterity. The LCM system allows one-step procurement of selected human cell populations from a section of complex, heterogeneous tissue. LCM has been used successfully to obtain pure populations of cancer cells from both frozen and paraffin-embedded tissues, stained or unstained, for the molecular analysis of macromolecules. LCM is capable of isolating single cells, making it possible to procure pure populations of neoplastic cells from lesions less than 1 mm in diameter without encroaching upon adjacent nonneoplastic cells. Using this technique, matched normal epithelium, stroma, benign, preneoplastic neoplasia, and cancer cells from the same specimen have been isolated successfully.

4.2 Target Specific Detection

Following technologies are covered under target-specific detection.

4.2.1 Tumor Antigen Markers: Techniques to Detect Autoantibodies

The identification of tumor antigens that elicit an antibody-based immune response may be useful in cancer screening and eventually in immunotherapy. The contribution of PTMs to the detection and identification of cancer biomarkers is significant. One approach is to rely on the immune system to help identify proteins that are synthesized by tumor cells that may be immunogenic. It may be possible to detect antibodies against the proteins that can be used as biomarkers. This is a simple approach that can be very productive.

There are three proteins that are immunogenic in cancer – beta-tubulin3 in neuroblastoma, annexin I and II in lung cancer, and calreticulin in liver cancer – that have been investigated to determine whether they can be used for early detection. For example, there appears to be some promise for using antibodies to annexin in the early detection of lung cancer. Studies on serum from patients in the carotene and retinol efficacy trial (CARET) indicated that 3 of 10 patients who progressed to lung cancer had antibodies to annexin a year before diagnosis.

4.2.2 Techniques for Detecting Glycoproteins

The global study of proteins has many unique difficulties that set it apart from comprehensive studies of genes and transcripts. First, the behavior of proteins is determined by the tertiary structure of the molecule. Any assay based on protein

binding depends on maintaining the native conformation of the protein. This limits the systems that can be used to capture protein targets in affinity-based assays. Second, the detection of low-abundant proteins poses a particular challenge, especially given that the dynamic ranges of proteins in biological systems can reach parts per million or greater. An amplification system analogous to the polymerase chain reaction is yet to be developed for protein studies. Furthermore, the behavior of proteins may or may not be governed quantitatively. Protein regulation often is based not on synthesis and degradation but on reversible modifications such as acetylation, for example. Compounding the difficulty is the fact that RNA splicing can produce highly homologous splice variants that differ in function. Nonetheless, protein science has advanced to the point that some of these hurdles can be overcome.

Protein profiles change because of infection with viruses associated with cancer. For example, individuals chronically infected with the hepatitis B or C virus (HBV, HCV) are at high risk for developing hepatocellular carcinoma (HCC), with disease progression occurring relentlessly over many years. The diagnosis of HCC usually occurs at late stages in the disease, when there are few effective treatment options and the prognosis is very poor. The latency period (up to 20 years), together with clearly identified at-risk populations, provides opportunities for earlier detection that will allow more timely and effective treatment of this devastating cancer. 2DGE was utilized to test the hypothesis that changes in the amount of certain serum polypeptides, or changes in their post-translational modifications, can be used to predict the onset of HCC. Advances in the standardization of 2DGE, together with automation of critical steps such as image analysis, permit the reproducible resolution of thousands of polypeptides per run. Serum polypeptides from individuals at different stages on the disease continuum are being resolved by 2DGE to identify those that change with disease progression. Polypeptides found by this method can be characterized further by MS. In addition, investigators are exploring the potential for changes in the glycan structure of certain polypeptides to serve as a marker for disease progression.

The proteomic approach is expected to facilitate identification of the best indicators and biomarkers of the progression of HCC. Information also may be obtained about the pathobiology of the disease process. It has been demonstrated that *N*-nonyl-deoxynojirimycin (*N*-nonyl-DNJ), a modified glycan, contains an antiviral activity designated to a function other than that of an impact on glycoprocessing. This idea was tested by experiments showing that *N*-nonyl-deoxygalactojirimycin (*N*-nonyl-DGJ), an alkyl derivative of galactose with no impact on glycoprocessing, retains anti-HBV activity. The data suggest that *N*-nonyl-DGJ exerts its antiviral action at a point before the virus is encapsulated and may prevent the proper infectivity of the HBV pregenomic RNA.

Tumor markers shed into the serum have been sought as a means to identify individuals at risk for developing cancer. An alteration in the oligosaccharides associated with glycoproteins is one of the many molecular changes that accompany malignant transformations. The methodology used to assess these alterations, however, has been hampered by several factors, including insensitive techniques that require large sample amounts, poor quantitation, and the lack of accurate information about the relative quantitation of

all of the oligosaccharides that are present. As a result, the systematic and thorough structural analysis of all of the oligosaccharides associated with particular proteins from the tissues of cancer patients has not been carried out. Since specific alterations in oligosaccharides typically are used in histology studies to differentiate between cancerous and noncancerous cells, the potential for oligosaccharides to serve as biomarkers in noninvasive methodologies remains a promising, but unexploited, area. Attempts are being made to explore oligosaccharide structure and disease-state relationships using a new robust technology platform that employs fluorescent high-pressure liquid chromatography (HPLC) analysis of sugars to quantitate every oligosaccharide present (abundance of >0.1% in the total glycan pool) in protein samples. Some of the markers that have been identified to date, such as fucosylated glycoform of alpha fetoprotein, have altered glycosylation patterns in the disease state.

4.2.3 Activity-based Protein Profiling

The activity-based protein profiling (ABP) technology is utilized to directly measure protein functions in complex proteomes. The goal of this approach is to develop activity-based chemical probes (ABPs). Regarding enzymatic activity and the role of PTMs, there are three significant enzyme types that have become the focus of research in this area: proteases (zymogens, endogenous inhibitors), kinases (autoinhibitory domains), and phosphatases (autoinhibitory domains, endogenous inhibitors).

The challenge of ABP is in identifying active sites on specific enzymes that guide their chemical activity and finding chemical reactive groups that label and bind the active sites in complex proteomes. The first enzyme class targeted with this approach was the serine hydrolases (SHs), a large and diverse enzyme family involved in a variety of pathophysiologic processes, including blood clotting, angiogenesis, neural plasticity, peptide hormone processing, T-cell immunity, reproduction, cancer, emphysema, and plant-parasite interactions.

Inhibition of SHs can be achieved by the ABP fluorophosphonate (FP) reagents. A study of breast and melanoma cancer cell lines indicated that it is possible, using cluster analysis, to characterize cell lines based on enzymes by subcellular distribution and tumor of origin. In this study, one cluster each of breast and melanoma cells was identifiable. A third cluster formed that had one breast line, one melanoma line, and one line of unknown origin and shared the property of being invasive. This suggested that cell lines may cluster by invasive properties rather than by tumor of origin. This indicated the existence of a dedifferentiation phenotype.

In melanoma cell lines, sialyl acetylesterase (SAE) actively reacted with the ABP and caused PTMs. Another example was that invasiveness-related serine hydrolase (IRSH), an integral membrane enzyme upregulated in invasive cancer cells from several tumor types, is upregulated in invasive cancer lines independent of tumor origin. A number of documentations indicate that mRNA expression in a disease like cancer does not correlate with protein expression mainly because protein expression is regulated not by changes in the level of expression but by its modifications. Some proteins that are regulated posttranslationally have a message level different from activity level, which is indicative of posttranslational regulation. Whether any of the SHs upregulated in invasive cancers is required for their aggressive properties

is presently unknown. A global analysis of SH activities provides proteomic information of sufficient quantity and quality to permit the phenotypic classification of cancer cells; invasive and noninvasive cancers exhibit nearly orthogonal serine hydrolase activity profiles; secreted and membrane enzymes are better predictors of cancer phenotype than are cytosolic enzymes. The information obtained from cell-line system will be useful in identifying markers from tumor. It is also emphasized here that the assays described above can be used by any clinical laboratory for the rapid and affordable screening of a variety of tumors.

4.3 Other Technologies

Some other technologies to detect markers are also utilized for cancer diagnosis.

4.3.1 Genomics

DNA-based markers include mutations, loss of heterozygosity (LOH), microsatellite instability, DNA hypermethylation, mitochondrial DNA mutations, and detection of cancer-associated viral and bacterial DNA. Lung cancer is used as an example here (Fig. 2). The development of lung cancer requires repeated insults of carcinogens, mainly from tobacco smoke, into the lungs over a long period of time. The carcinogenesis process takes a few decades and results in the accumulation of multiple molecular abnormalities in cells, which is the basis for malignant transformation and tumor progression. There is evidence that genetic abnormalities occur in the early carcinogenic process in the lungs of chronic smokers and that certain abnormalities may persist for many years after smoking cessation. Genetic and molecular alterations, such as mutations in the *p53* tumor suppressor gene and *K-ras* protooncogene, promoter hypermethylation of the *p16* tumor suppressor gene, and LOH in multiple critical chromosome regions have been identified frequently in early stage lung cancers. Investigators are exploring the possibility of using these alterations as biomarkers in the early detection of and in risk assessment for lung cancer. With the completion of human genome mapping and advances in high-throughput technologies, the discovery of molecular alterations in the carcinogenic process is accelerating. A substantial effort is now underway to conduct large-scale cooperative discoveries and validations of biomarkers for early cancer diagnosis. It is anticipated that molecular marker-based novel diagnostic strategies will be developed and merged into clinical practice to augment current, inefficient tools for diagnosing patients with early stage lung cancer. Different examples of biomarkers used to detect a variety of cancers are discussed in Section 5.1.

4.3.2 Epigenomics

The development of a malignant phenotype in a given cell is accompanied and often preceded by an accumulation of DNA lesions. Until recently, it was firmly believed that this change was exclusively genetic, that is, affecting the actual base pairing of the double stranded DNA (e.g. base pair mutations, deletions, LOH, microsatellite instability, and so on.). However, changes in the structure of the DNA and its scaffolding proteins may, without disrupting the base pairing of the DNA, interfere with the normal physiologic functions of the DNA. These changes are referred to as ''epigenetic'' and include mechanisms like nuclear compartmentalization, stable feedback loops, differential replication timing, heritable chromatin structures such as histone acetylation and

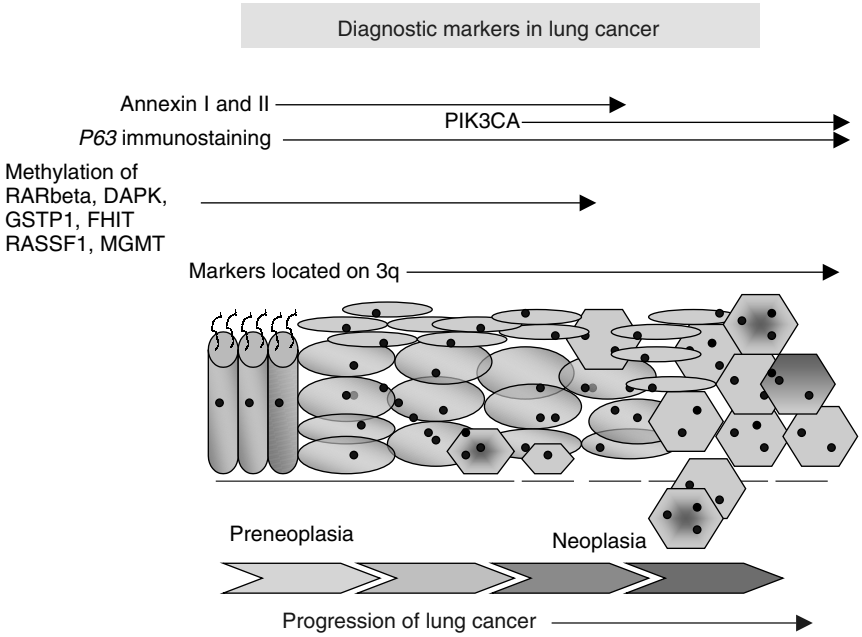

Fig. 2 Potential biomarkers to predict lung cancer. Epithelial carcinogenesis is thought to be a multistep process involving sequential activation of oncogenes as well as the inactivation of tumor suppressor genes in a clonal population of cells. These genetic changes generate concomitant phenotypic changes in the tumor cells that promote survival and proliferation. A number of genetic alterations in oncogenes and tumor suppressor genes have been reported in a variety of tumor types. Because conventional histology is unable to predict which lesions are likely to progress to cancer, the development of molecular-based approaches to identify predictive genetic changes would greatly improve the potential for early detection, prognostication, and intervention. In the figure, markers expressed in different stages of tumor development are shown. As the cancer progresses, the shape of cells changes and many cells become multinucleated.

foremost DNA methylation. Epigenetics is the study of processes that establish metastable (i.e. somatically heritable) states of gene expression without altering the DNA sequence. A number of epigenetic markers can be utilized for cancer diagnostics. As an example, we have presented potential epigenetics biomarkers in colon cancer development (Fig. 1). In large part, the field of epigenetics addresses processes that affect DNA methylation and/or chromatin structure to establish metastable, but somatically heritable, states of gene expression. Thus, epigenetic phenomena can be defined as changes in the genetic material (specifically the genomic DNA and chromatin) that alter the regulation of gene expression in a manner that is somatically heritable (and sometimes heritable through the germline) but is nonmutational, that is, does not involve changes in the DNA sequence.

In the normal mammalian genome, methylation occurs only at the cytosines 5′ to guanosines at the CpG dinucleotides. The CpG dinucleotides have been depleted progressively from the eukaryotic genome over evolution via spontaneous

deamination. The remaining CpGs have a very high frequency of methylation-facilitating chromatin arrangements to render most of the genome late replicating and repressed for the transcription of repeated regions. CpG islands, small stretches of DNA, do contain the expected frequency of CpGs, however. The methylation-protected regions generally are located in the promoter regions. In a normal human, up to 90% of CpGs are methylated.

It has been suggested that the lack of methylation might be a prerequisite for active transcription. Only two exceptions to this rule have been reported: fully methylated CpG islands in the silenced allele for specific imprinted autosomal genes and multiple silenced genes on the inactivated X-chromosomes of females. Another emerging concept indicates that deacetylation of histone is the primary step that results in the recruitment of methyltransferase to the CpG islands and in hypermethylation of the promoter. To develop cancer-prevention strategies, it will be essential to identify factors that regulate the activity of deacetylation. Extensive research is needed in this area, as targets for chemoprevention could emerge from such studies. Furthermore, epigenetic regulation occurs early in the development of cancer and provides an opportunity to develop intervention approaches that prohibit further cancer development.

Concurrent aberrant methylation patterns have been evaluated as tools in the management of patients with cancer. The predictive value, the therapeutic manipulation, and the prognostic significance of aberrantly methylated gene loci have been tested in hematological as well as in solid neoplasia of adults and children. Importantly, methylation does not only hold the potential for being ''just another'' biomarker, but also, as it can be reverted chemically, for being a phenomenon that holds great promise for therapeutic exploitation.

Technologies used to detect epigenetic alterations include methylation-specific PCR, MethyLight DNA analysis, restriction landmark genomic screening (RLGS), methyl cytosine amplification (MCA), and immunoassays to detect histone acetyl transferase. Nanochips with multiple epigenetic marker genes are also being developed in academic and private institutes.

4.3.3 RNA-based Assays

There are various ways of detecting cancer cells by analyzing RNA. Studies of differential mRNA expression can be informative, but mRNA levels do not always correlate with protein levels. Proteins often are subject to proteolytic cleavage or to posttranslational modifications, such as phosphorylation or glycosylation. Cancer-detection strategies that target expressed proteins are becoming increasingly popular because proteomic approaches characterize the modified or unmodified proteins that are involved in cancer progression. It is critical to preserve samples in appropriate condition – for example, extremely low-storage temperature – for RNA analysis. Such requirements make RNA-based assays somewhat difficult to apply in clinical settings.

4.3.4 Posttranslational Modifications

Posttranslational modifications (PTMs) are an integral part of gene regulation. PTMs of proteins, not detected through RNA analysis, may occur at different stages of tumor development, which is indicative of early or late events of transformation. During PTM, a protein is modified either in the endoplasmic reticulum or the Golgi

complex by undergoing phosphorylation, acetylation, glycosylation, palmitoylation, myristilation, ubiquitination, farensylation, methylation, or sialylation. Specific genes are turned on or off at the onset of initiation, development, and progression of diseases such as cancer. PTMs have been reported for the key steps in tumor progression, such as cell cycle check point and apoptosis. There is a need for research to identify PTM markers at an early stage of cancer development and for developing prevention strategies.

4.3.5 Imaging

Imaging is a powerful tool for cancer diagnosis. Mammography is currently regarded as the most-effective method for early detection of breast cancer. Nevertheless, it is estimated that up to 30% of breast lesions are missed during the screening process. In addition, when radiologists classify mammograms as suspicious, and biopsies are performed to confirm malignancy, only about 10 to 30% of mammographically identified suspicious lesions are positive. The use of magnetic resonance imaging (MRI) offers a great opportunity to develop alternative ways to diagnose breast cancer. The image resolution is substantially higher and true three-dimensional identification is present. Cancers are shown to enhance relative to other tissue following the administration of different agents such as gadolinium-diethyl-enetriamine pentaacetic acid (Gd-DTPA).

The sentinel node technique is widely employed in cases of breast cancer diagnosis. Different detector systems have been used, but several problems have occurred in clinical practice. One such problem is the difficulty in accurately detecting the sentinel node within the auxiliary soft tissue. This problem is even more pronounced in cases of abdominal and thoracic tumors. The innovative imaging probe (IP) allows primary tumors and secondary lesions, if appropriately radiolabeled, to be visualized on a monitor. The IP is a small, portable, high-resolution gamma camera used in radioguided surgery and can be applied optimally for minimally invasive surgery in breast cancer treatment. The collection of more data would improve identification techniques for carcinoma and parenchyma, fibroadenoma, and benign proliferative changes.

Another powerful technology is functional imaging that can address as yet unresolvable questions about cancer biology in both basic sciences and clinics. Combining functional imaging with anatomical criteria of the disease can be beneficial in the management of cancer. Functional CT describes the use of existing technologies and conventional contrast agents to capture physiological parameters that reflect the vasculature of tumors and other tissues. The technique is readily incorporated into routine conventional CT examinations. In tumors, the physiological parameters obtained provide an *in vivo* marker of angiogenesis. In addition to serving as a research tool, functional CT has clinical applications in tumor diagnosis, staging, risk stratification, and therapy monitoring, including the characterization of pulmonary nodules, detection of occult hepatic metastases, grading of cerebral glioma, and monitoring of antiangiogenesis drugs. Since software is available for the development of multisided CT systems, functional CT is poised to have a significant impact on the imaging of patients with cancer.

Computer-assisted diagnosis (CAD) has been applied to mammography and chest radiography to improve diagnostic

accuracy and has the potential to improve the accuracy of MRI for detecting nodal metastases in women with newly diagnosed breast cancer. Clinical researchers should design future trials to incorporate plans for collecting and analyzing molecular markers.

5 Challenges in Cancer Diagnostics: Validation of Biomarkers

Our ability to predict the biology of premalignant lesions has been limited by controversial clinical terms, inaccurate and subjective assessments because of the lack of well-defined criteria for grading interexaminer variability, and, most importantly, the lack of genotypic-/phenotypic-based biomarkers. It is somewhat paradoxical that the spectacular achievements made in the last few years in defining molecular genetic alterations in cancer have not translated into effective strategies for screening and early diagnosis. Methods other than nonrandomized clinical trials must be established to evaluate and validate biomarkers for clinical application during the early stages of investigation. Validation of new biomarkers by traditional clinical trials will be unfeasible owing to cost, time required for follow-up, rapidly changing technologies, variations in treatments, and the large number of biomarkers expected to be discovered.

5.1 Biomarkers as Surrogate End Points

Biomarkers can also be used as surrogate endpoints; however, it is necessary that the following criteria are satisfied: (1) modulation or elimination of the risk marker must correlate with a decrease in cancer incidence; (2) the marker must be modulated by chemopreventive agents; and (3) the marker must be a determinant of outcome. Risk markers are usually used as surrogate outcomes in order to detect the effect of a prevention intervention more rapidly than waiting for the definitive outcome. Biomarkers for colon cancer are most likely to be found in stool specimens.

Utilization of surrogate endpoint biomarkers (SEBs) addresses many of the limitations seen in large chemoprevention trials. However, there always has been a question of whether the surrogate endpoint is a valid step along the pathway to carcinogenesis. In this regard, three types of SEBs that are being used in chemoprevention research are: (1) *Pathologic Biomarkers* are premalignancies, such as colon polyps, that are known to progress to cancer in some cases; (2) *Drug Effect Biomarkers* are dynamic endpoints of a direct drug-to-target effect, such as aspirin, which inhibits the production of prostaglandins. (3) *Biological Biomarkers* are proteins, genes, or quantitative cellular processes that are used to predict cancer diagnosis or risk. These can also be divided into *Process Biomarkers*, such as those involved in pathway-derived carcinogenesis or regulatory endpoints, and *Screening Biomarkers*, which are derived from proteomic assessment.

Another major challenge is to make diagnostic assays high throughput, easy to adopt, and applicable to multiple samples. With the advancement of knowledge in the biomarker field, it is possible to achieve these goals. Furthermore, the knowledge gained in diagnostics will be useful in approaches, such as prevention, which relies on interventions during early phases of carcinogenesis to reduce the incidence of invasive cancer and, ultimately, to reduce cancer-related morbidity and mortality.

5.2 Biomarker Validation

For biomarker validation, information on quantifying biomarker endpoints is essential. There should be strict laboratory standards and procedures for completing assays. Validation is very difficult unless newer technologies are used to increase statistical power. One newer approach using technology is to develop pattern recognition with quantitative computed imaging techniques. There is a need for reliable biomarker panels for use in large population studies that meet the following specifications: (1) serum is the preferred sample for the assay; (2) the assay should not be expensive; (3) there must be an easy method for quality control; (4) there must be an algorithm because proteins, which are multiclonal, will vary among different types of cancer.

Novel biomarkers must be validated prior to general use. Sensitivity, specificity, and predictive value must be determined through the use of body fluids, paired tumors, and surrounding tissue from a wide variety of cancers. A large number of samples from individuals with known characteristics should be processed to minimize the problems of confounding and to avoid forged associations. Prior to field testing, it should be established that the biomarker is truly in the path of pathogenesis and not simply the result of an adaptive response. Case-control studies on stored samples should be employed to test biomarker efficiency. While the emerging technologies show great promise, care must be taken to define and establish references or baseline profiles from a variety of tissues (including normal tissues) or body fluids.

Extensive animal studies may help to refine human testing prior to screening. The biomarker assay should be reproducible to avoid mislabeling individuals as false positives or false negatives and to provide sufficient time before clinical diagnosis. Sample sources such as urine and stools for DNA make it important to evaluate techniques and methods for extraction. A biomarker should be tested in the population intended for ultimate use because tests for early detection often require a higher specificity than do tests in clinical diagnosis. With regard to early detection and prevention strategies, biological samples should be screened for a cluster or pattern of markers and for substantial accuracy in performing risk assessment. The positive predictive value of a test can be assessed and labeling of individuals as either false positives or false negatives can be minimized by using a panel of biomarkers.

Despite extensive efforts to improve the diagnosis and treatment of patients with lung cancer over the past three decades, the overall survival rate of patients with the disease remains dismal. Because lung cancer takes a few decades to develop, early diagnosis of the disease or identification of truly high-risk populations may provide an opportunity to successfully cure or prevent the disease. Recent advances in understanding the biological basis of lung tumorigenesis have provided new tools for detecting malignant cells and the process of malignant transformation and progression. Along with the identification of molecular abnormalities in early lung tumorigenesis, advanced molecular analytic technologies have emerged that may facilitate the development of rapid and effective methods for early diagnosis and risk assessment.

The use of functional imaging to develop ''functional'' approaches to diagnosis and therapy needs further investigation. Many methodologies exist for the acquisition of

primary data on the efficacy of imaging technologies. A form of economic cost-effectiveness modeling called iterative decision analysis can be used to set research and service priorities. Cancer clinicians need to take an increased role in functional imaging research because they have considerable expertise in the development and use of treatments that modify cell and tissue function.

Microscopic examination of tissue detects a disease after it has developed and is important in forecasting tumor behavior and prognosis. Additional procedures, however, are essential for early detection.

With regard to the use of biomarkers as risk factors or for detecting preneoplastic lesions, several criteria must be met as described below:

- The variance of the detection tests and the intra and interlaboratory variance must be known.
- The biomarker and its assay must provide acceptable predictive accuracy for risk or for the presence of cancer.
- The biomarker must be differentially expressed in normal, premalignant, and in tumor tissue.
- The assay of the biomarker should be simple enough to be accommodated in clinical settings.

In cancer prevention, intervention is achieved through the use of pharmaceuticals, vitamins and minerals, or other chemicals that reduce cancer risk. Choosing the targets for chemoprevention research is of the utmost importance. There should also be evidence of a nongenetic component (i.e. acquired mutations) to the carcinogenesis process in the target disease. Another important issue is the ability to obtain tissue to study the disease, and there must be some amount of preclinical (e.g. mechanism-of-action, *in vitro* studies, and preclinical *in vivo* data) evidence to support the research.

A number of limitations exist in chemoprevention trials. Some studies indicate a screen-to-accrual rate of 5 to 10%. A significant barrier in the process is the number of participants needed to reach a cancer endpoint to a trial. Large numbers of participants are needed for a significant period of time (10–20 years) if cancer is used as an endpoint. In addition, the design of chemoprevention trials is very complex.

6 Summary

Early cancer detection is one of the best defenses against cancer. Emerging technological advancements in proteomics and genomics are allowing us to extract larger amounts of information from smaller and smaller samplings. In the future, single-cell analysis and nanotechnology may allow us to study cancer heterogeneity and the effects of complex cellular interactions precisely. The early results in microarray-based gene expression analysis are painting a detailed portrait of cancer that illustrates the individuality of each tumor and allows familial relationships to be recognized through the identification of cell types sharing common expression patterns. As proteomic and genomic tools continue to develop, it will be essential to integrate information from several analyses into a common framework to develop a more complete understanding of cancer diagnostics and its implications in cancer-risk assessment and therapeutics. Efforts are continuing to identify new markers that may be useful in cancer diagnosis. Once good markers of risk are identified, it may eventually be possible to perform risk-based screening in which the frequency of

screening is a function of the patient's risk based on the family history and other risk factors.

Keywords

Anencephaly
Exposure of the interior of the brain to the outside, with absence of the skull vault, resulting from failure of neural tube closure in the future brain.

Closed spina bifida (or dysraphism)
Skin-covered spinal lesions in which the lowest portion of the spinal cord fails to become separated from adjacent tissues during embryonic development, leading to spinal cord tethering inside the vertebral canal.

Craniorachischisis
The most severe NTD in which most of the brain and the entire spinal cord remain open, as a result of failure of the initiating event of neurulation (Closure 1).

Exencephaly
An early developmental form of anencephaly, in which the persistently open cranial neural folds appear everted and ''overgrown.'' Later in gestation, degeneration of the exposed neural tissue results in the ''flat skull'' appearance of anencephaly.

Hydrocephalus
Increase in cerebrospinal fluid pressure within the cavities of the brain, often associated with spina bifida.

Myelomeningocele
Alternative term for open spina bifida. The spinal cord is open (myelo-), and the meninges emerge from the defect in a cystic lesion (meningocele). An open spinal cord without a covering meningeal sac is called *myelocele*.

Neural plate
A layer of ectodermal cells on the back of the early embryo that undergoes folding and fusion to produce the neural tube, the precursor of the entire brain and spinal cord.

Neural tube defects
The group of birth defects comprising spina bifida, anencephaly, and craniorachischisis that result when the neural tube fails to complete closure during embryogenesis.

Neural tube
The tubular structure formed in the early embryo by folding and fusion of the neural plate in the dorsal midline to produce the precursor of the brain and spinal cord.

Neuropore
A transient ''holelike'' opening in the neural tube at which neural tube closure is undergoing completion.

Neurulation
The embryonic process by which the neural tube is formed. In higher vertebrates, neurulation comprises primary events, characterized by neural folding, and secondary neurulation in which the caudal neural tube forms by hollowing of a cord of cells to create a tubular structure.

Open spina bifida (spina bifida aperta)
Exposure of the interior of the spinal cord to the outside environment. This definition encompasses the pathological terms myelocele and myelomeningocele.

Spina bifida is usually grouped together with the closely related conditions anencephaly and craniorachischisis, to form the category of congenital malformations known as *neural tube defects* (NTDs). NTDs affect approximately 1 in every 1000 pregnancies, equating to a worldwide prevalence of around 120 000 pregnancies with NTDs per year. Hence, NTDs represent one of the commonest, most severe birth defects in humans. The term NTDs reflects the origin of the malformations. In normal development, the *neural plate*, the precursor of the brain and spinal cord in the early embryo, undergoes folding and fusion to form the *neural tube*. If neural tube closure fails in the developing spine, the result is open spina bifida (also called *myelomeningocele or myelocele*; Fig. 1(a)–(d)), a defect in which the interior of the spinal cord remains open to the outside, rather than being covered by the bony vertebrae and skin. The exposed nervous tissue degenerates before birth so that babies born with open spina bifida are often paralysed and lack sensation below the level of the lesion. They may exhibit urinary and faecal incontinence, and have associated defects such as *hydrocephalus* (Fig. 1(e)). If the neural tube fails to close in the embryonic brain, the resulting birth defect is initially described as *exencephaly* (Fig. 1(b)), in which the neural folds appear everted. Later in gestation, degeneration of the neural tissue converts the defect to *anencephaly*, in which the interior of the skull is exposed owing to loss of the open brain and failure of the skull roof to develop. Fetuses with anencephaly do not survive beyond birth, and are often stillborn or die during pregnancy. If the entire neural tube fails to close, from brain to low spine, this is referred to as *craniorachischisis* (Fig. 1(f)–(h)), a uniformly lethal condition. Closed spina bifida (also called *spina bifida occulta*) represents the mild end of the NTD spectrum. The lowest part of the spinal cord fails to separate from adjacent tissues during development, a defect that can produce weakness of the legs or urinary incontinence. Surgical intervention may be required in order to free the spinal cord within the vertebral canal, relieving pressure on the spinal nerve roots.

1
Neurulation: A Multiphase Embryonic Event

NTDs (neural tube defects) result from failure of neurulation, the embryonic event responsible for formation of the neural tube. Neurulation comprises a series of coordinated cellular behavior, beginning with differentiation of neurectoderm from lateral ectoderm. Concomitantly, the neural plate narrows medio-laterally and lengthens rostro-caudally by the process of convergent extension, with neuroepithelial and underlying mesodermal cells moving toward the midline and intercalating along the rostro-caudal axis. Subsequently, neural folds form at the edges of the neural plate, which then elevate, with bending at

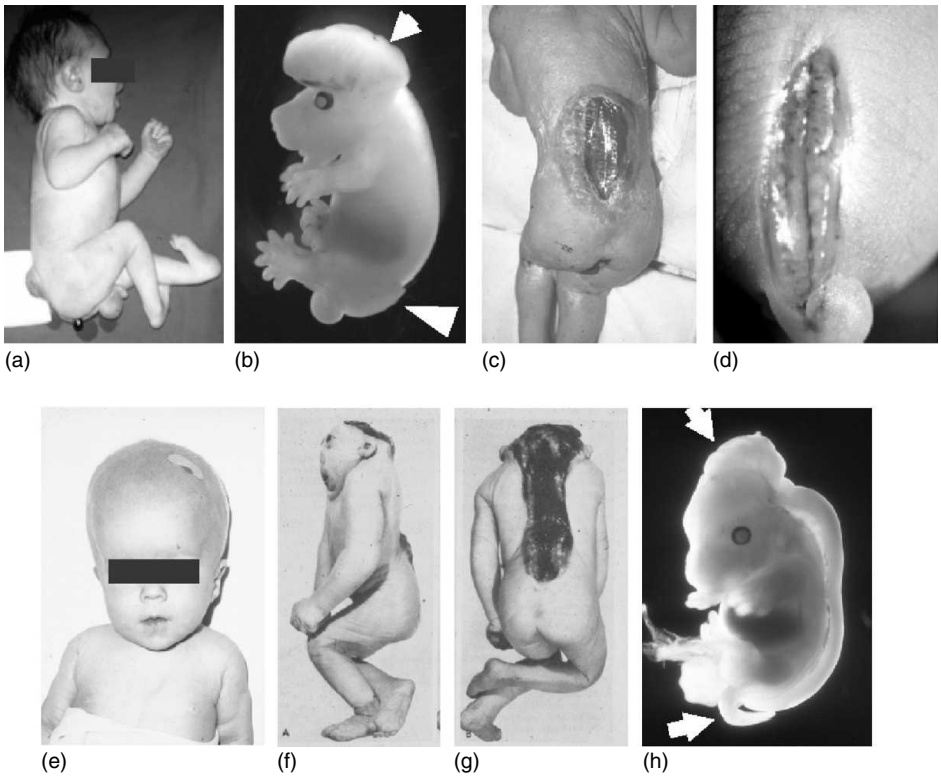

Fig. 1 The spectrum of NTDs in humans and mice. (a) Myelomeningocele in a human neonate; (b) exencephaly (arrow) and open spina bifida (arrowhead) in an E15.5 mouse embryo homozygous for the *curly tail* mutation; (c) myelocele in a human neonate; (d) open spina bifida in an E18.5 mouse fetus. Note the close similarity between these mouse and human NTDs; (e) hydrocephalus, with marked expansion of the cranial vault; (f, g) craniorachischisis in a human fetus from sideview (f) and back view (g). Most of the brain and spine are open; (h) craniorachischisis in an E15.5 mouse embryo homozygous for a mutation of *Celsr1*. The neural tube is open between the arrows, affecting most of the brain and the entire spine, as in the human defect. Parts (b, h) modified from Copp, A.J., Greene, N.D.E., Murdoch, J.N. (2003) *Nat. Rev. Genet.* **4**, 784–793; Part (c) from Copp, A.J. (1999) *Encyclopaedia of Life Sciences/www.els.net* Nature Publishing Group, London, UK; Part (d) from Stiefel, D., Shibata, T., Meuli, M., Duffy, P., Copp, A.J. (2003) *J. Neurosurg. (Spine)* **99**, 206–213.

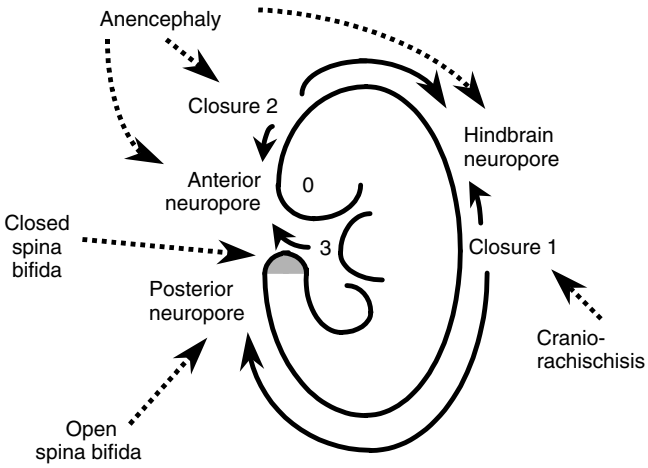

Fig. 2 Schematic summary of the successive initiation events of mouse neurulation (Closures 1, 2, and 3), the direction of spread of closure from the initiation sites (solid arrows), and the sites of completion of closure (anterior, hindbrain, and posterior neuropores). The tail bud region (red shading) is the site of secondary neurulation, which follows immediately after closure of the posterior neuropore. The main types of NTD that result from failure of the different components of neurulation are indicated by the dotted arrows. Modified from Copp, A.J., Bernfield, M. (1994) *Curr. Opin. Pediatr.* **6**, 624–631. (See color plate p. xxv).

precise dorso-ventral locations, until the tips of the neural folds come into contact in the dorsal midline. The apposed neural folds adhere and then fuse, with subsequent remodeling of the epithelia, to create the neural tube and covering surface ectoderm.

1.1 Rostro-caudal Sequence of Neurulation Events

In the mouse, neural tube closure is initiated at the hindbrain/cervical boundary (Closure 1), and then proceeds concurrently in the future brain and spinal regions (Fig. 2). Brain closure is initiated independently at the forebrain/midbrain boundary (Closure 2) and at the extreme rostral end of the forebrain (Closure 3). Closure between these initiation sites occurs simultaneously, culminating in the completion of cranial neurulation at the anterior and hindbrain neuropores. The spread of closure caudally along the spinal axis leads to progressive closure of the posterior neuropore, marking the end of primary neurulation.

While the neurulation process has been studied most closely in the mouse, human neurulation appears quite similar. Closures 1 and 3 certainly occur in human embryos, whereas there is disagreement between authors about the occurrence of an event comparable to mouse Closure 2. In fact, even in the mouse, Closure 2 is a variable event, with some inbred strains exhibiting the closure rather caudally, within the midbrain, whereas other strains undergo Closure 2 more rostrally, within the

forebrain. In these latter strains, Closures 2 and 3 may be located extremely close together, making the two events difficult to distinguish from each other. This variant of mouse Closure 2 resembles the human situation, where a distinct Closure 2 event has been inconsistently observed.

2 Causation of Spina Bifida and Other NTDs

NTDs have a multifactorial aetiology, with both genetic and environmental influences playing an important role.

2.1 Genetic Factors

The genetic component of NTD etiology is revealed by the dramatically increased risk among women who have had a previous NTD pregnancy. Compared with the average background prevalence of 0.5 to 2 per 1000 pregnancies, the recurrence risk rises after one affected pregnancy to around 1 in 25 and after two affected pregnancies to about 1 in 10. These average figures relate to live born or therapeutically aborted NTD cases, and may underestimate the true recurrence rates. Significant numbers of NTDs are lost as spontaneous abortions early in pregnancy, suggesting that the true incidence, and perhaps also the recurrence rate, of NTDs may be higher than commonly quoted. The finding that the risk of an NTD pregnancy is also increased in first-degree relatives of an index case, with risk declining in second- and third-degree relatives is further evidence of a significant genetic component to the etiology of NTDs.

In the mouse, NTDs occur as a result of mutations in more than 80 different genes. This suggests that normal functioning of a large number of genes is necessary to ensure normal neural tube development. It predicts, moreover, that human NTDs are unlikely to result from the action of just a single gene, but ultimately may prove to be etiologically related to many genes. Hence, NTDs are probably heterogeneous both morphologically, in terms of the varying level of the body axis that is primarily affected, and also etiologically in terms of their precise genetic causation.

Despite the evidence for a strong genetic etiology, no major causative genes have yet been identified for human NTDs. The strongest link is to the gene encoding 5,10-methylene tetrahydrofolate reductase (MTHFR), an enzyme involved in intracellular folate metabolism. A polymorphic, thermolabile variant of MTHFR (caused by the C677T mutation) has a higher frequency among NTD cases and their families than among normal controls in Dutch and Irish populations. Although a link with NTDs is more difficult to demonstrate in other human populations, a meta-analysis of the worldwide data showed an overall significant association between MTHFR and NTDs. The C677T mutation of MTHFR appears to contribute to the overall risk of NTDs, particularly when combined with low vitamin B_{12} status or with homozygosity for the A66G variant of the enzyme methionine synthase reductase. Hence, genetic variations in folate metabolism may predispose to NTDs.

Several of the genes implicated in mouse NTDs have been examined in human NTD cases, but to date, only rare mutations have been identified. There are several possible reasons for this negative finding. First, most of the mouse NTD–causing mutations act only in homozygous form, while heterozygotes are usually normal. This contrasts with human genetic disease

where haplo-insufficiency is the commonest cause of clinical phenotype. With a few exceptions, such as cystic fibrosis, homozygotes for specific genetic defects are usually rare and contribute little to the overall burden of genetically determined human disease. Second, many of the mouse NTD mutants are embryonic lethals. Given the extremely high level of pregnancy wastage in humans, it is probable that most disadvantaged human embryos fail to survive to late gestation. Third, it seems likely that gene–gene interactions, rather than single-gene effects, are most likely to play a major role in the etiology of human NTDs.

Gene–gene interactions have been well documented in the mouse. For example, while the *curly tail* (*ct*) mutation and the unrelated *splotch* (Sp^{2H}) mutation each cause spina bifida in homozygotes, mice doubly heterozygous for both mutations ($ct/+$; $Sp^{2H}/+$) also have NTDs. Embryos of genotype ct/ct; $Sp^{2H}/+$ exhibit particularly severe spina bifida. Translated to the human situation, this suggests that NTDs may result most commonly from the coming together in a single individual of two or more different genetic variants, which provides the interaction necessary to disturb neurulation. If many genes are required for successful neurulation, as in the mouse, a large number of possible combinations of genetic variants might be capable of producing NTDs. This could yield a ''sporadic'' occurrence of NTDs at a relatively high frequency, as is observed in all human populations.

2.2 Environmental Factors

Epidemiological studies point to a likely role for nongenetic factors, as well as genetic influences, in the etiology of NTDs. For example, the relatively high prevalence of defects among pregnancies in low socioeconomic groupings has led to the suggestion that nutritional factors may be of significance. This idea receives support from the finding of a preventive effect of folic acid supplementation on the occurrence and recurrence of NTDs.

As with the genetic aspects of NTD etiology, rather few environmental factors have been shown definitively to cause human NTDs. It is now widely accepted that exposure to the anticonvulsant sodium valproate during the early weeks of pregnancy, when the neural tube is closing, raises the risk of spina bifida to around 1.5 to 3%, a 15- to 30-fold increase in prevalence compared to background incidence. An elevated risk of NTDs has also been reported with carbamazepine, another anticonvulsant. Apart from these drug associations, the only other well-defined environmental association relates to the uterine milieu associated with maternal diabetes mellitus. The frequency of NTDs (like many other birth defects) is increased severalfold in pregnancies of diabetic mothers.

A variety of exogenous agents, when applied to rodent embryos, exert teratogenic effects with the production of abnormalities including NTDs. The majority of NTD-causing agents are drugs, chemicals, or other substances extraneous to pregnancy. For example, administration of sodium valproate either to the pregnant female or to the embryo *in vitro* produces NTDs although the principal defect produced in rodent embryos is exencephaly, not spina bifida as in humans. Other well-known NTD-producing teratogens include metals such as arsenic and cadmium, drugs including cytochalasins and alkaloids, and physical agents including radiation and

hyperthermia. Apart from exogenous teratogenic agents, a number of molecules derived from metabolism cause NTDs, particularly in the context of maternal disease condition. Elevated concentrations of glucose and ketone bodies, as found in diabetes mellitus, increase the risk of NTDs, a finding that parallels the predisposition to NTDs in human diabetic pregnancy. Moreover, an excess or deficiency of retinol (vitamin A), and particularly its active metabolite retinoic acid, are also potent causes of NTDs. Retinoic acid is produced endogenously in the embryo and is essential for a variety of developmental processes. An imbalance in signaling via retinoic acid receptors leads to NTDs, among other defects.

As with gene–gene interactions, environmental influences on nervous system development seem most likely to operate in the context of varying genetic susceptibility. This idea has been particularly well illustrated by studies in which different inbred mouse strains, each representing a unique genetic background, were found to exhibit varying susceptibility to cranial NTDs caused by teratogenic agents, including valproic acid. The genes that mediate this strain-specific variation in NTD predisposition are not yet known, whereas the developmental basis of the strain variation has been traced to a polymorphism in the precise pattern of cranial neurulation. Inbred strains differ in the position along the rostro-caudal axis of the developing brain at which the Closure 2 closure event occurs. While the majority of strains exhibit Closure 2 at the midbrain/forebrain boundary, others have this event occurring more caudally within the midbrain (e.g. DBA/2 strain), or more rostrally within the forebrain (e.g. NZW strain). Experimental studies have shown that strains with a caudal Closure 2 point are relatively resistant to exencephaly (Fig. 3), whether caused by teratogenic or genetic influences, whereas strains with a rostral Closure 2 point are relatively prone to exencephaly. Hence, the precise position of Closure 2, as dictated by the genetic background, sets the risk level of a strain in its interaction with either teratogenic or genetic factors that can cause cranial NTDs.

Teratogenic agents can also interact directly with the single-gene effects to modulate the frequency or severity of NTDs. For example, the low natural frequency of exencephaly in the *curly tail* strain is elevated by the administration of all-trans-RA although, interestingly, the frequency of spina bifida in this strain is actually reduced by low-dose RA. This example demonstrates that environmental agents can exert sharply contrasting effects, either exacerbating or ameliorating, upon interaction with a genetic predisposition.

3 Developmental Mechanisms of Spina Bifida and Other NTDs

Of the more than 80 genes demonstrated to be necessary for successful neurulation, only a few have been studied in sufficient detail to reveal how the genetic requirement is mediated developmentally. Recent studies have led to an improved understanding of two aspects of neurulation: the initial closure event (Closure 1), whose failure leads to the severe NTD, craniorachischisis, and the progressive closure of the spinal neural tube, which yields spina bifida when defective. In both cases, specific signaling pathways have been shown to be critical for successful neurulation. More diverse cellular events appear crucial for cranial neural tube closure,

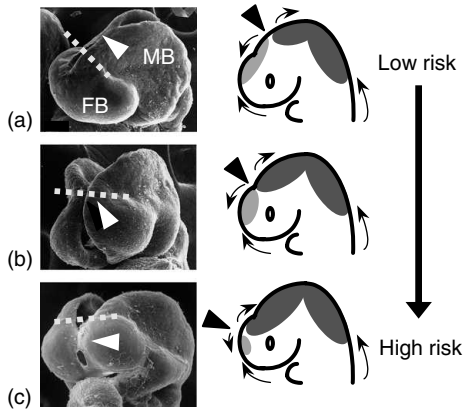

Fig. 3 Variations in position of Closure 2, in the future brain of different inbred mouse strains, in relation to the risk of exencephaly and anencephaly. Left panel shows scanning electron micrographs of embryonic brains from the left frontal view. Dotted lines indicate the forebrain/midbrain (FB/MB) boundary. Arrowheads point to the site of initiation of Closure, which is located caudal to the FB/MB boundary in the DBA/2 strain (a), at the FB/MB boundary in the CD1 strain (b), and rostral to the FB/MB boundary in the NZW strain (c). Middle panel summarizes diagrammatically this variation in Closure 2 morphology. Red shading indicates open neural folds caudal to the site of Closure 2, whereas green shading indicates the anterior neuropore, rostral to Closure 2. Arrows indicate direction of neural tube closure. Right panel shows an increasing risk of exencephaly correlated with a progressively more rostral position of Closure 2. The reason for this correlation is that the midbrain region, which lies at the apex of the cranial flexure, is mechanically the least favorable brain region for neural tube closure, and is aided in its closure by a caudal Closure 2 position (a) but hampered in its closure by a rostral Closure 2 position (c). Modified from Fleming, A., Copp, A.J. (2000) *Hum. Mol. Genet.* **9**, 575–581. (See color plate p. xxiii).

whose failure results in the development of anencephaly.

3.1 Initiation of Neurulation: Role of Planar Cell Polarity Signaling

The initial closure event (Closure 1) occurs when the neural folds fuse at the level of the future hindbrain/cervical boundary (Fig. 2). If Closure 1 fails, the embryo develops with an extensively open neural tube, from midbrain to low spine (craniorachischisis, Fig. 1(f)–(h)), although the forebrain is closed, as Closure 2 occurs normally in such embryos.

Recently, the cell movements of convergent extension, which occur from the stage of gastrulation onward, have been found to be essential for initiation of neural tube closure. Convergent extension requires signaling via the so-called planar cell polarity pathway, a noncanonical Wnt signaling pathway in which extracellular signals are transduced via cell-surface frizzled receptors and intracellular proteins of the dishevelled family (Fig. 4). Downstream events in this pathway include the activation of cytoskeleton-related proteins such as RhoA and the Jun-N-terminal kinases (JNKs).

In *Xenopus*, misexpression of dishevelled, or its interacting partner protein strabismus, prevents convergent extension, yielding embryos with an abnormally short, broad neural plate that fails to complete neural tube closure. This defect in *Xenopus* closely resembles the NTDs

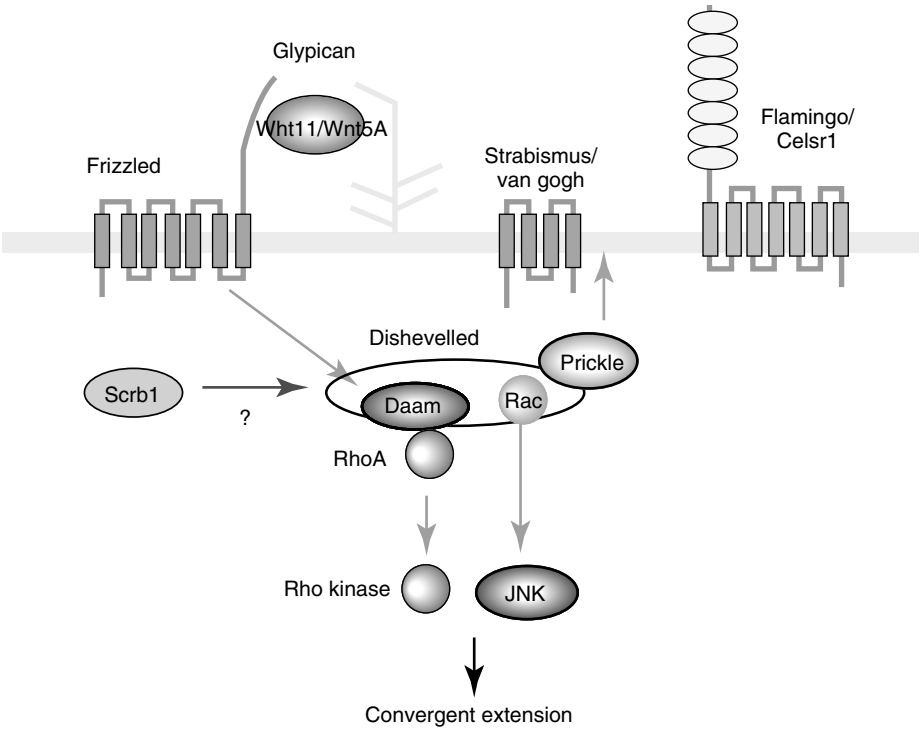

Fig. 4 The noncanonical Wnt (planar cell polarity) signaling pathway, which has been implicated in the regulation of convergent extension cell movements and initiation of neural tube closure (Closure 1). Mutations in the *strabismus/van gogh* (*Vangl2*), *Flamingo/Celsr1*, *Scrb1*, and *Dishevelled* genes all disturb Closure 1 in the mouse embryo, leading to the severe NTD craniorachischisis. Downstream signaling is thought to be via Rho kinase and/or jun-N-terminal (JNK) kinase. Modified from Ueno, N., Greene, N.D.E. (2003) *Birth Defects Res. (Part C)* **69**, 318–324.

in mouse embryos homozygous for the *loop-tail, circletail,* and *crash* mouse mutants, and in embryos lacking function of both *dishevelled1* and *dishevelled2* genes. In each of the mouse mutants, the neural plate is abnormally broad and has a nonbending region intervening between the neural folds, in contrast to the well-defined median hinge point of normal embryos. Although the neural folds elevate relatively normally, they are located too far apart to achieve closure (Fig. 5). Hence, convergent extension is required to establish a neural plate of width that is compatible with the medial bending essential for the initiation of closure.

The critical role of planar cell polarity in mammalian convergent extension and initiation of neurulation has become clear from recent genetic findings. All of the mouse mutants with failure of Closure 1 have proven to harbor mutations in components of the planar cell polarity pathway: *loop-tail* mice are mutant for the *strabismus/Vangl2* gene, *circletail* mice have mutations in *Scrb1,* and *crash* mice are mutant for *Celsr1,* a homologue of the *Drosophila* gene *flamingo*. It is striking,

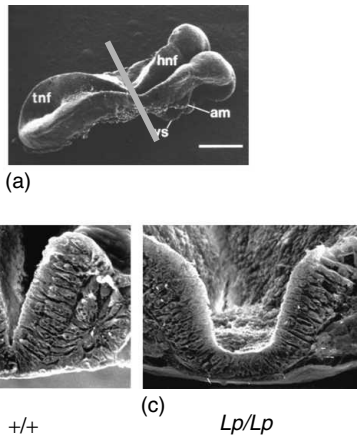

Fig. 5 Initiation of neurulation (Closure 1) in the mouse embryo, as studied by scanning electron microscopy. (a) Whole E8.5 embryo demonstrating the approaching neural folds approximately half way along the body axis, indicating the incipient Closure 1 event. This event occurs at the boundary of the hindbrain and cervical regions. (b, c) Sections transverse to the body axis as indicated by the red line in (a). The wild type embryo (b) shows ''Mode 1'' morphology with bending at a compact midline hinge point, and straight lateral neural folds. The homozygous *loop-tail* (*Lp/Lp*) embryo (c) shows a disturbance of the midline, which is broader than normal, without a compact bend in the neural plate. Although the neural folds elevate, laterally, they are not able to appose and fuse in the midline, leading to craniorachischisis in mutant embryos. Scale bar represents 0.25 mm (a) and 0.03 mm (b, c). Modified from Copp, A.J., Brook, F.A., Estibeiro, J.P., Shum, A.S.W., Cockroft, D.L. (1990) *Prog. Neurobiol.* **35**, 363–403; Greene, N.D.E., Gerrelli, D., Van Straaten, H.W.M., Copp, A.J. (1998) *Mech. Dev.* **73**, 59–72. (See color plate p. xxiv).

therefore, that the only group of mouse mutants that develop craniorachischisis all affect the same signaling pathway, suggesting a crucial role for the establishment of planar cell polarity in ensuring the successful initiation of neural tube closure.

3.2
Regulation of Neural Plate Bending: Mechanisms of Spina Bifida

In birds and mammals, bending of the neuroepithelium occurs at two specific sites in the neural plate: at the ventral midline (the median hinge point, MHP) and at paired dorsolateral bending sites near the junction of the neural plate and surface ectoderm (the dorsolateral hinge points, DLHPs). MHP bending creates the ''neural groove,'' with a V-shaped cross-section, while DLHP bending creates longitudinal furrows that bring the lateral aspects of the neural plate toward each other in the dorsal midline.

Closure in the spinal region of the mouse embryo involves the progressive ''zippering'' of the neural tube down the spinal axis, until the posterior neuropore completes its closure at the future upper sacral level at E10. As the upper spine is forming, at embryonic day (E) 8.5, the closing neural folds exhibit an MHP but no DLHPs. By early E9.5, the neural plate begins to bend at DLHPs in addition to the MHP and, at the lowest spinal levels (at E10), the MHP disappears and the neural plate bends only at DLHPs. Hence, there is a complete switch from closure based on midline bending to closure dominated by dorsolateral bending during the course of mouse spinal neurulation (Fig. 6(a)–(d)).

Dorso-ventral molecular interactions have been implicated in the regulation of neural plate bending along the spinal region of the mouse embryo. A concentration-dependent influence of Shh, originating from the notochord and

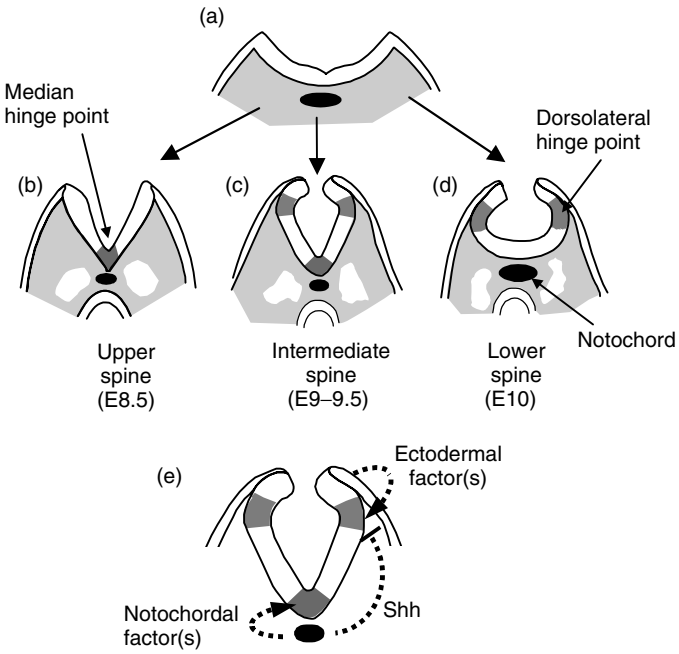

Fig. 6 Changing morphology of neurulation as neural tube closure progresses along the spinal region of the mouse embryo. The neural folds elevate from an initially flat morphology (a). In the upper spine (b), the neural plate bends only in the midline (Mode 1), at the median hinge point (MHP; see also Fig. 5(b)). In the intermediate spinal axis (c), both midline and dorsolateral bending are observed (Mode 2), whereas in the low spine (d), midline bending is lost and only dorsolateral hinge points (DLHPs) are observed (Mode 3). This changing pattern of neurulation is regulated by dorso-ventral patterning molecules (e). Notochordal factor(s) induce the MHP, while Shh, a secreted notochordal factor, inhibits DLHP formation. Factor(s) from the surface ectoderm induce DHLPs. As neurulation progresses along the spinal axis, the strength of notochordal signaling diminishes, with consequent loss of MHP-mediated bending and the emergence of DLHP-mediated neural tube closure. Modified from Ybot-Gonzalez, P., Cogram, P., Gerrelli, D., Copp, A.J. (2002) *Development* **129**, 2507–2517.

floor plate, patterns neuronal differentiation events along the dorso-ventral axis of the neural tube. BMPs (bone morphogenetic proteins) and Wnts, from the dorsal ectoderm, oppose Shh influence and promote dorsal patterning events. The MHP is induced by signals from the notochord, as demonstrated by experiments in which notochordal development was suppressed, with prevention of MHP formation. Shh, emanating from the notochord, may participate in the induction of the MHP, although midline bending is not completely abolished in Shh null embryos, suggesting a role for other, as yet unknown, notochordal inductive factors. Interestingly, although suppression of the notochord prevents MHP formation, the

neural tube still closes, suggesting the existence of a ''default'' mechanism of neural tube closure that operates in the absence of Shh influence (Fig. 6(e)).

An explanation for this observation has come from experimental studies with cultured mouse embryos, which show that Shh emanating from the notochord serves to inhibit DLHP formation in the upper spine of normal embryos. This inhibitory Shh influence counteracts a positive effect of the surface ectoderm that induces bending of the dorsal neural plate; in the absence of surface ectoderm, DLHPs are not formed. BMPs are possible mediators of this ectodermal influence, although this is speculative at present. As the wave of spinal neurulation passes down the body axis, the strength of Shh signaling from the underlying notochord lessens, enabling DLHP formation to ''break through'' at lower spinal levels. DLHP formation in the lower spine can be inhibited by local release of Shh peptide, demonstrating the negative regulation of dorsolateral bending by Shh. In the absence of Shh, as in notochordless embryos or in embryos genetically null for Shh, DLHP formation is de-inhibited and ensures closure of the neural tube at all levels of the body axis.

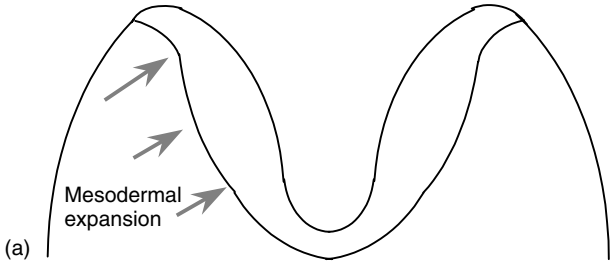
Hence, the precise pattern of bending of the neural plate during spinal neurulation is dictated by mutually inhibitory signals from the notochord and surface ectoderm. This conclusion is supported by the finding that mutations that increase the strength of Shh signaling (e.g. knockout of the *Patched1* gene) inhibit neural tube closure, presumably owing to an increased strength of Shh-mediated inhibition of DLHP formation, which is incompatible with the completion of closure of the posterior neuropore.

3.3 Molecular Regulation of Cranial Neurulation

Cranial closure is more susceptible to disturbance than spinal closure in the mouse, as evidenced by the increased occurrence of exencephaly compared to spina bifida among knockouts and mutants with NTD phenotypes. Similarly, more teratogenic agents induce mouse cranial NTDs than spinal NTD. Studies of gene knockout mice with cranial NTDs suggest several cell and molecular processes that appear crucial for the successful closure of the cranial neural folds. These include expansion of the cranial mesenchyme, function of the actin cytoskeleton, emigration of the cranial neural crest, and regulated balance between cell proliferation and cell death (Fig. 7). Knockout mice in which these events are disrupted have cranial but not spinal NTDs, suggesting that spinal neurulation is relatively independent of these mechanisms.

3.3.1 Cranial Mesenchyme

As the cranial neural folds elevate, there is a marked expansion of the cranial mesenchyme, with cell proliferation and a striking increase in extracellular space. This causes the neural folds to take on a bulging (biconvex) appearance, particularly in the midbrain. Mice with loss of function of the *Twist* or *Cart1* genes have cranial NTDs in which the principal defect appears to be a reduction in the proliferation and expansion of the cranial mesenchyme. Both genes are expressed in the mesenchyme, and chimeric analysis in the *Twist* mutant demonstrates that exencephaly develops only if there is a high proportion of $Twist^{-/-}$ cells in the cranial mesenchyme.



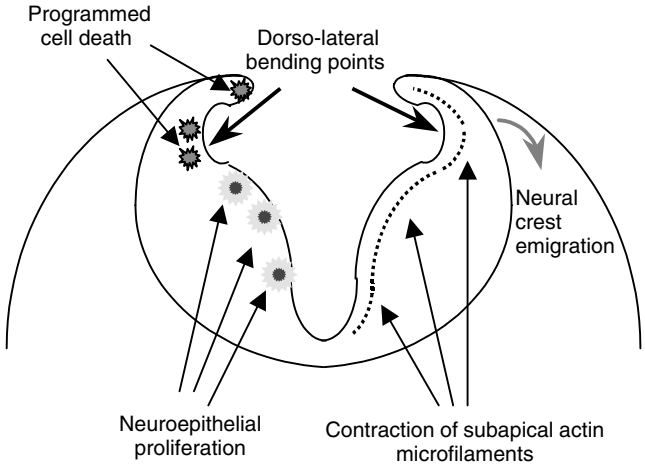


Fig. 7 Summary of the cellular and morphogenetic processes that are required for successful neural tube closure in the future brain. Cranial neural folds in the midbrain of the mouse embryo elevate initially with a biconvex morphology (a). Subsequently, dorsolateral bending occurs, causing the tips of the neural folds to converge on the midline (b), ensuring fusion and completion of cranial neurulation. Mesodermal expansion appears to be the most important morphogenetic factor in the initial elevation of the neural folds (a). However, the later stages of cranial neurulation require a number of additional processes including a functional actin cytoskeleton, successful initiation of neural crest emigration, precisely regulated programmed cell death and continuation of regulated neuroepithelial cell proliferation, with postponement of neuronal differentiation until after closure is complete (b). Defects in each of these processes are seen in one or more of the 80 gene knockout mice with NTDs. In each case, cranial neural tube closure fails and embryos develop exencephaly/anencephaly. Modified from Copp, A.J., Greene, N.D.E., Murdoch, J.N. (2003) *Nat. Rev. Genet.* **4**, 784–793.

3.3.2 Actin Cytoskeleton

In the second phase of cranial neural tube closure, the edges of the biconvex neural folds ''flip around'' and adopt a biconcave morphology, approaching the dorsal midline where fusion occurs to complete brain closure. This second neurulation phase is highly dependent on the actin cytoskeleton. Mice lacking the filamentous actin-associated protein shroom develop exencephaly, revealing a dependence of cranial neurulation on the actin microfilaments. This finding is consistent with *in vitro* studies in which rodent embryos are treated with cytochalasins, drugs that disassemble actin microfilaments. Cranial neural tube closure is inhibited by cytochalasins, whereas spinal neurulation proceeds to completion in the presence of these drugs. Hence, both genetic and nongenetic interventions demonstrate that the requirement for actin microfilaments is specific to cranial neural tube closure.

3.3.3 Neural Crest Emigration

The transition from biconvex to biconcave neural plate morphology also seems dependent on the initiation of cranial neural crest migration. In the midbrain and hindbrain, neural crest cells detach from the apices of the neural folds and start migration well in advance of neural tube closure, in contrast to the spinal region where neural crest emigration follows completion of neural tube closure. Mice overexpressing the gap junction protein connexin 43 exhibit marked cranial neural crest migration defects, and also develop exencephaly. Similarly, neural crest emigration and dorsolateral bending of the cranial neural folds are delayed in cultured rat embryos treated with chondroitinase ABC, to digest preexisting chondroitin sulphate. These findings suggest that neural crest emigration is a prerequisite for cranial neural tube closure, perhaps by increasing the flexibility of the lateral neural plate.

3.3.4 Programmed Cell Death

There is growing evidence to implicate a precise regulation of programmed cell death (apoptosis) in cranial neurulation. Dying cells occur within the dorsolateral regions of the cranial neural plate and at the tips of the fusing neural folds. Moreover, studies of knockout mice demonstrate that either an increase or decrease in the amount of this apoptosis is detrimental for cranial neurulation. Exencephaly develops in knockouts such as the *Apaf-1*, *caspase 9*, and *p*53 genes, which have reduced apoptotic cell death, and in knockouts of *AP-2*, *bcl10*, and *Tulp1*, which show increased apoptosis in the cranial neural folds. The precise role played by cell death in cranial neurulation is not clear. Dorsolateral cell death may synergize with neural crest cell emigration, to ''loosen'' the cranial neuroepithelium, thereby allowing the conversion from a biconvex to biconcave neural fold morphology. Additionally, apoptosis at the tips of the neural folds may play a quite different role. Once the apposing neural folds have contacted and adhered, midline epithelial remodeling is needed to break the continuity between neuroepithelium and surface ectoderm on each side, enabling the neural tube roof and its covering ectoderm to be formed at the midline. Inhibition of apoptosis using the peptide Zvad-fmk produces spinal NTDs in the chick embryo, probably by preventing this dorsal midline remodeling. Hence, apoptosis may play a dual role in cranial neurulation.

3.3.5 Neuronal Differentiation

The onset of neuronal differentiation occurs only after neural tube closure is

complete, during normal development, and this temporal sequence appears essential for successful cranial neurulation. Gene knockouts such as *RBP-Jκ*, *Hes1*, and *Numb*, which affect the Notch and related signaling pathways, exhibit failure of cranial neurulation in association with the premature onset of neuronal differentiation in the neural plate. The early appearance of differentiating neuroepithelial cells in these mutants might interfere with neurulation by rendering the neural plate mechanically inflexible, by interfering with the release of neural crest cells, or by inhibiting adhesion of the neural folds.

3.3.6 Cell Proliferation

Excessive cell proliferation has been implicated in some NTD mutants, such as mice with overexpression of Notch3, which produces increased numbers of neural progenitor cells in association with exencephaly. Neuroepithelial ''overgrowth'' has been suggested in relation to the exencephalic brains of other mutants but, when analyzed in detail, a normal or even lengthened cell cycle has generally been observed in exencephalic brains. It remains to be determined whether a disturbance of cell proliferation *per se* is a common cause of cranial NTDs.

4 Prevention of NTDs by Folic Acid and Other Vitamins

Much interest was stimulated by the finding that supplementation with folic acid can prevent a proportion of NTDs, estimated at around 70%, in the UK Medical Research Council Vitamin Research Group randomized clinical trial of NTD recurrence. Folic acid prevented 40 to 85% in a nonrandomized supplementation study in China, and there were no cases of NTD among 2394 pregnancies that received a folic acid–containing multivitamin supplement, compared with six out of 2310 unsupplemented pregnancies, in a randomized controlled trial of NTD occurrence in Hungary. Fortification of bread flour with folic acid in the United States has been associated with a 19% reduction in the prevalence of NTD. The variation in the proportion of cases prevented by folic acid in the various studies may relate to the differing doses of folic acid used. Indeed, NTD risk appears related to the log (serum folate level) in humans. Nevertheless, reports of successive NTD pregnancies in a single family despite high-dose folate intake suggest that a proportion of NTD cases may be resistant to folate, perhaps reflecting heterogeneity of etiology, with some subtypes of NTD being sensitive to folic acid whereas others are folate resistant.

4.1 Animal Models of Folate-preventable NTDs

Supporting evidence for the existence of folic acid–sensitive and folic acid–resistant NTDs comes from studies of mouse genetic mutant strains with NTDs. In some mutants, NTDs can be prevented by folic acid (e.g. *splotch, crooked tail, Cart1, Cited2*). Moreover, exencephaly has been reported in mice lacking the folate transport protein encoded by the gene *Folbp1*. This gene knockout causes lethality around the time of neural tube closure, hampering an assessment of whether *Folbp1* is essential for neural tube closure. However, treatment of the pregnant dams with folic acid rescues survival in these mice, and a proportion of the surviving homozygous knockouts exhibit exencephaly later in gestation. It

is interesting that spina bifida is not part of the *Folbp1* knockout phenotype, even though folic acid appears to prevent both spina bifida and anencephaly among human NTDs. Moreover, analysis of the folate receptors α and β have revealed no association with the NTD phenotype in a series of human pregnancies.

Other genes that are involved in folate transport and metabolism have not yet been associated with neural tube closure defects in mice. For example, MTHFR, which has been implicated as a risk factor in human NTDs (see Section 4.1), does not cause NTDs when inactivated in mice.

4.2 Folate-resistant NTDs and Inositol as an Adjunct Therapy

While there is ample evidence from experimental studies to support a preventive effect of folic acid on NTDs, some mouse NTD models have proven insensitive to folic acid therapy, for example, the *curly tail, axial defects*, and *ephrin-A5* mutants. *Curly tail* is the best-characterized mouse model of folate-resistant NTD, with information available on the embryonic mechanism of neural tube closure failure. Recently, *Ghl3* was identified as a strong candidate for the gene mutated in *curly tail*. The spinal NTDs in this mutant are not altered in frequency by administration of folic acid, folinic acid (5-formyl tetrahydrofolate), Pregnavite Forte F (a multivitamin preparation active in preventing human NTDs), or methionine. Interestingly, however, a significant reduction in frequency of spinal NTD, with a particular reduction in the incidence of the most severe defect lumbosacral spina bifida, is seen after maternal administration of *myo*-inositol and *D-chiro*-inositol. *Curly tail* embryos are also at increased risk of developing exencephaly under conditions of inositol deficiency, compared to nonmutant embryos.

The preventive effect of inositol on spinal NTD in *curly tail* mice is mediated via intracellular signaling through the inositol phospholipid cycle, by stimulation of protein kinase C (PKC) activity. A role for PKC is demonstrated by the ability of the PKC agonist, 12-O-tetradecanoylphorbol-13-acetate (TPA), to substitute for *myo*-inositol in preventing the NTD. On the other hand, the broad spectrum inhibitor of PKC action, GF109203X, blocks prevention both by *myo*-inositol and TPA. Recent studies have identified PKCβI, γ or ζ, but not other isoforms of PKC, as essential for mediating the preventive effect of inositol on NTDs. The PKCβI isoform is required for stimulation of cell proliferation in the hindgut endoderm of the caudal region of *curly tail* embryos, which counteracts the genetically determined cell proliferation defect, and rescues the phenotype.

Hence, the pathway that mediates the preventive action of *myo*-inositol on NTD in the *curly tail* mouse is becoming understood. The finding of inositol as an alternative to folic acid for prevention of mouse NTDs raises the possibility of a novel future adjunct therapy to folic acid for use in human pregnancy.

5 Conclusions

Spina bifida is a member of the group of congenital malformations known as NTDs. A combination of studies of humans and animal models is contributing to our increasing knowledge of the etiology of NTDs, with identification of key genetic and nongenetic influences, and a growing appreciation of the types of interaction that

promote or ameliorate the risk of NTDs. Study of mouse models is shedding light on the developmental mechanisms that underlie the different categories of NTDs, with marked variations in mechanism along the body axis. Primary prevention of NTDs is now a reality with introduction of folic acid, which has a preventive effect on a proportion of NTD cases. Folate-resistant NTDs require other strategies for prevention, and inositol appears promising in studies of one-mouse model.

Keywords

Axon
The long narrow part of a neuron that carries action potentials away from the cell body and finally transmits signals to other neurons via synaptic connections. The axon forms the presynaptic component of many synapses.

Dendrite
The part of a neuron that is a cytoplasmic extension of the cell body. Groups of dendrites often have a main trunk, for example, the apical dendrite, and many branches. This structure is called a *dendritic tree*. Dendrites form the postsynaptic component of most synapses.

PDZ Domain
A protein–protein interaction domain named for homologous regions in Postsynaptic protein 95, *Drosophila* discs-large, and zona-occludens 1.

Postsynaptic Neuron
The neuron on the receiving side of information flow across a synapse.

Postsynaptic Density
An electron dense region found immediately underneath the postsynaptic plasma membrane.

Presynaptic Neuron
The neuron on the transmitting side of information flow across a synapse.

Synapse
The specialized zone of contact at which one neuron communicates with another.

Synaptic Cleft
The small extracellular region between sites of signaling between neurons.

Synaptic Terminal or Bouton
The end of an axon that contains neurotransmitters stored in vesicles, which are released when the vesicles fuse with the membrane.

The brain consists of billions of neurons, cells that have specialized morphologies for precise communication. This communication takes place at synapses, which can be chemical or electrical. The focus here is chemical synapses, sites where one neuron, the presynaptic neuron, sends chemical signals called *neurotransmitters* that bind to receptors on the second, or postsynaptic, neuron. This binding then transduces signals to the postsynaptic neuron, allowing communication to be propagated.

To understand how the brain functions and how signaling processes go awry during pathophysiological conditions, the players in this signaling must be identified. Recently, neurobiologists have uncovered the identities of proteins that play a major role in initiating release of neurotransmitter from the presynaptic neuron. They have also elucidated the role of scaffolding proteins in setting up signaling networks in the postsynaptic neuron. Although by no means comprehensive, this article summarizes currently accepted theories that form the basis for our understanding of neurotransmitter-mediated neuronal signaling.

1
Parts of the Neuron

1.1
Functional Domains of the Neuron

The neuron is a polarized cell; that is, it has specialized domains that allow for information flow. The largest part of the neuron is the cell body or soma. The soma contains organelles necessary for basic cellular function. For example, the nucleus, responsible for gene expression, resides in the soma. In addition, unlike other parts of the neuron, if the soma is damaged, the neuron cannot recover and will die. Besides playing a role in basic function, the soma can serve to receive synaptic signals from other neurons.

On most neurons, there are multiple branches that often derive from the soma. These branches are known as *dendrites*. The majority of synapses occur on dendrites, which typically form the postsynaptic component of synapses. The extent

of dendritic branching can be influenced by factors such as learning, which increases branching, or alcohol exposure or disease, which often decrease the number of dendrites. This has important physiological implications. Neurons that have a greater number of branches have more sites for receiving information from other neurons. In fact, in conditions such as mental retardation or Alzheimer's disease, there are fewer branches on neurons in the hippocampus and cortex, areas important for learning and memory.

A neuron also must contain a site where it can send signals to other neurons. The part of a neuron that is specialized for carrying signals long distances from the cell body and storing and releasing neurotransmitters from its terminals is called the *axon* (Fig. 1). It is a single extension, or neurite, from the cell body that is much longer and thinner than the dendrites. Like dendrites, axons may have branches, or collaterals, which generally occur at a distance from the soma. In addition, when neurons are damaged, axons may ''sprout'' or branch to form new synapses and replace those destroyed. Neurotransmitters are stored in vesicles that are present in the tips of axons. These tips swell and are called *synaptic boutons* or *terminals*. When the neuron transmits signals to its postsynaptic partner, the vesicles fuse with the plasma membrane and the neurotransmitter is dumped into the synaptic cleft.

A majority of axons, especially those with longer diameters, are myelinated; that is, they are covered with a lipid and proteinaceous sheath. The myelin serves as an electrical insulator. There are small areas of myelinated axons that do not have myelin that are called *Nodes of Ranvier*. The myelin and the Nodes of Ranvier work together to increase the speed that electrical impulses travel along axons. Thus, heavily myelinated axons conduct electric impulses faster than unmyelinated axons. For example, neurons involved in the sensation of pain have unmyelinated axons, while neurons involved in tactile sensations, such as vibration and two point discrimination, are myelinated. This results in a time delay between pain sensation and other touch sensations associated with a stimulus.

1.2 The Synapse

Neuronal communication occurs at the synapse. Synapses consist of a presynaptic component, which is the axon terminal, the synaptic cleft, which is typically

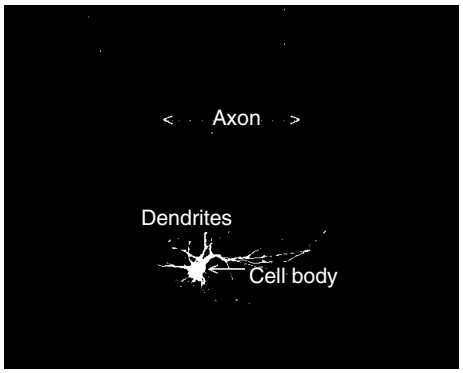

Fig. 1 Functional domains of a neuron. Morphology of a single hippocampal neuron is shown by expression of a fluorescent protein inside of the neuron. Dendrites, which contain sites for receiving information, are relatively short protrusions from the cell body, or soma. There is a single axon that extends from within the figure to outside of the figure and reenters the field shown. The axon is the longest protrusion from the cell body. This axon releases neurotransmitter at its end, which is not visible in the figure.

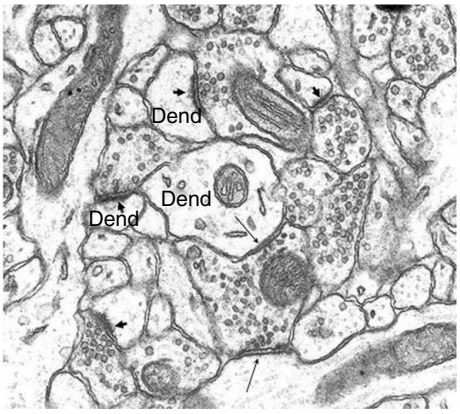

Fig. 2 Electron micrograph of mammalian central nervous system synapses. Note that axons contain small dark circles. These are vesicles filled with neurotransmitters. Some dendrites are denoted as dend. Thick arrows indicate asymmetric excitatory synapses. Note the dark electron rich areas just beneath the postsynaptic membrane. These areas are postsynaptic densities. Thin arrows point to symmetric (GABA) synapses. Note the absence of thick postsynaptic densities at these synapses. Electron micrograph is courtesy of Dr. Kristin Harris, Synapse Web, Medical College of Georgia, http://synapses.mcg.edu/

the small space between the two communicating neurons, and a postsynaptic component, which is typically a dendrite. As discussed above, neurotransmitter is released into the cleft, and it binds to receptors on the postsynaptic site. This binding triggers a signaling cascade in the postsynaptic neuron, which can lead to changes in the postsynaptic neuron or release of neurotransmitter from this postsynaptic neuron at other synapses sending signals to yet another neuron. Thus, depending on how synapses are arranged in the brain, signaling networks are established that lead to physiological responses.

Electron microscopists noticed that not all synapses are alike. There are two main forms. Synapses are classified as symmetric or asymmetric on the basis of the thickness of the postsynaptic density (Fig. 2). Inhibitory synapses (those that use GABA or glycine as a neurotransmitter) possess an axon terminal active zone and a postsynaptic region that are of equal thickness. Hence, they are symmetric synapses. Excitatory synapses of the CNS, the majority of which use glutamate as a neurotransmitter, have a thicker electron-dense region adjacent to the postsynaptic plasma membrane, making the thickness of the postsynaptic density greater than that of the presynaptic density. Hence, excitatory synapses are termed *asymmetric*.

2 The Presynaptic Component of a Synapse

2.1 Neurotransmitters

2.1.1 Classes of Neurotransmitters

There are two types of neurotransmitters that can be used for neuronal communication: classical and nonclassical. There are four main criteria by which neurotransmitters are judged to be classical (Table 1). First, the neurotransmitter must be synthesized in the neuron. Second, the neurotransmitter must be present in the presynaptic terminal and released in amounts sufficient to exert an effect on the postsynaptic cell. In general, neurotransmitters are produced in the cytoplasm of the axon terminal and are taken up into vesicles by specific transporters. Third, the neurotransmitter must be in a chemically identifiable form and, when administered exogenously, it must mimic the effects of

Tab. 1 Criteria for classical neurotransmitters.

Criteria for classical neurotransmitters
1. The neurotransmitter must be synthesized in the neuron.
2. The neurotransmitter must be present in the presynaptic terminal and released in amounts sufficient to exert an effect on the postsynaptic cell.
3. The neurotransmitter must be in a chemically identifiable form and, when administered exogenously, it must mimic the effects of the endogenous neurotransmitter.
4. There must be some type of removal from the synaptic cleft.

the endogenous neurotransmitter. Fourth, there must be some type of mechanism for removal from the synaptic cleft. This removal can occur in a number of ways. Neurotransmitter can diffuse away from the cleft, thus making it inaccessible to the postsynaptic receptors. Alternatively, some clefts contain specific enzymes that degrade the neurotransmitter. Additionally, some neurotransmitters have a system for reuptake into the presynaptic terminal. Finally, glial cells and neurons have neurotransmitter transporters in their plasma membranes, which allow for the intact neurotransmitter to be taken up by either of these cell types. These mechanisms allow for finite action by the neurotransmitter on the postsynaptic cell.

Nonclassical neurotransmitters do not adhere to all of the main criteria discussed above. These neurotransmitters fall into two general groups: peptide neurotransmitters and gaseous neurotransmitters (Tab. 2). Peptide neurotransmitters are usually synthesized in the cell body, where they are packaged into vesicles and transported to the axon terminal. Peptides are usually synthesized as larger inactive precursor molecules, which are then cleaved to produce smaller active molecules. Like classical neurotransmitters, peptides are released into the cleft and are inactivated by either diffusion or enzymatic cleavage. *Gaseous neurotransmitters*, also sometimes referred to as *neuromodulators*, include nitric oxide and carbon monoxide. These transmitters are synthesized in the cytosol of the postsynaptic neuron in which they can then act on enzymes or binding proteins to participate in signaling in the postsynaptic neuron. Additionally, since they are gases, these neurotransmitters can diffuse across the membrane and to the presynaptic neuron. This is sometimes referred to as *retrograde signaling*.

2.1.2 The Main Classical Neurotransmitters in the Mammalian CNS

Catecholamines The catecholamines are derived from tyrosine and include dopamine (DA), norepinephrine (NE or noradrenaline), and epinephrine (E or adrenaline) (Tab. 2). DA acts as an inhibitory neurotransmitter in the central nervous system (CNS). NE can acts as an excitatory neurotransmitter when it binds to α_1 or β_1 receptors and as an inhibitory neurotransmitter when it binds to α_2 or β_2 receptors. Dopaminergic neurons produce DA when tyrosine is converted to L-DOPA by tyrosine hydroxylase (TH), which is then converted to DA by L-aromatic amino acid decarboxylase (L-AADC). If dopamine-β-carboxylase (DBH) is present, all DA is converted to NE; if DBH is not present, the neuron produces DA as a neurotransmitter. Similarly, if the neuron contains phenylethanolamine *N*-methyltransferase (PMNT), all NE is converted to E. Catecholamines are cleared from the cleft by transporters and are degraded by enzymes, such as monoamine oxidase (MAO).

In the past 15 to 20 years, there has been great interest in DA and its role in the control of voluntary movement. Deficiencies in DA lead to tremors and rigidity, often manifesting as Parkinson's disease. There has been a major effort to cure this disease. Patients with Parkinson's disease are often given L-DOPA, which relieves the symptoms for a short time. However, a severe side effect often occurs – Huntington's disease–like symptoms, which are frequently due to excess DA or L-DOPA. Alternatively, there has been some success in both animal models and humans with gene therapy. Since Parkinson's disease occurs because of a deficiency in TH, strategies have included grafting of fetal tissue, which can differentiate, express TH, and produce DA, or of fibroblasts genetically engineered to express TH. These strategies are still being refined.

In contrast to Parkinson's disease, an excess of DA is thought to contribute to schizophrenia, which manifests as irrational thought, delusions, and hallucinations. However, this disease is thought to be multifactorial. Other neurotransmitters, such as glutamate and acetylcholine, may also contribute to the pathophysiology of this disease.

Serotonin Serotonin is produced when tryptophan is metabolized by tryptophan hydroxylase, yielding 5-Hydroxy L-Tryptophan (5-HTP) (Tab. 2). 5-HTP is then acted upon by L-AADC to yield 5-hydroxytryptophan (5-HTT), or serotonin. Once released into the cleft, where it can bind to receptors on both the pre- and postsynaptic neuron, it is taken up by the neuron by a high-affinity transporter, and degraded in the neuron by MAO. Serotonin has an inhibitory effect when it binds to 5-HT_1 receptors and an excitatory effect when it binds to 5-HT_2, 5-HT_3, and 5-HT_4 receptors.

Serotonin is known to play an important role in regulating mood, sleep, and appetite. In fact, low levels of serotonin have been linked to depression. Pharmaceuticals used to treat depression usually target serotonin uptake, receptors, or degradation. They work to either increase serotonin levels or stimulate the serotonin receptor. Norepinephrine is also thought to work in concert with serotonin in regulating mood, so some of these agents also work to block reuptake or degradation of NE.

Acetylcholine Unlike the catecholamines and serotonin, the excitatory neurotransmitter acetylcholine (Ach) is not synthesized from an amino acid. Instead, the enzyme choline acetyltransferase acteylates choline using acetyl-CoA to form Ach (Tab. 2). After Ach is released into the cleft, it can be degraded by acetylcholinesterase present in the cleft to produce choline and acetic acid. The choline is then taken up by the neuron, where it is recycled for production of more Ach.

Ach plays a major role in movement, learning, and memory. It is the sole neurotransmitter found at the neuromuscular junction, the site of communication between motor neurons and muscles. Furthermore, excess Ach can lead to muscle paralysis. Deficits in Ach are known to contribute to Alzheimer's disease. Cholinergic forebrain neurons degenerate in this disease, resulting in learning and memory deficits.

Glutamate Glutamate is the major excitatory neurotransmitter in the mammalian CNS (Tab. 2). Glutamate is thought to be synthesized via metabolic pathways, such

as glycolysis. It is then sequestered in synaptic vesicles through a transporter. Furthermore, after being released into the synaptic cleft, it is transported back into the neuron via high affinity transporters. In addition, glutamate can be taken up by glia, where it is recycled.

Recently, there has been a great deal of focus on the role of glutamate in learning and memory. The dissociation of specific glutamate receptors from signaling pathways has resulted in abnormal learning in transgenic mice. Furthermore, mice that overexpress certain glutamate receptors learn faster and are considered ''smarter.''

Excess glutamate is released from presynaptic terminals under pathophysiological conditions such as ischemia, anoxia, or stroke. Overstimulation of glutamate receptors results in neuronal death. Thus, a fine balance between understimulation and overstimulation of glutamate receptors must be maintained for normal functioning of the brain.

Gamma-aminobutyric acid Gamma-aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the mammalian brain, and glycine is the main inhibitory neurotransmitter in the spinal cord. GABA is produced when α-ketoglutarate formed in Krebs cycle is transaminated to glutamate by the enzyme GABA-transaminase. Glutamate is then converted into GABA by a reaction catalyzed by glutamic acid decarboxylase (GAD). Thus, immunostaining for GAD distinguishes inhibitory neurons from excitatory neurons. GABA that is released into the synaptic cleft is taken up by both neurons and glia via high-affinity GABA transporters.

GABA is thought to play a role in the regulation of anxiety. Decreased activity of GABA is thought to lead to anxiety. Thus, antianxiety drugs, such as Valium, increase activity of GABA receptors. In addition, abnormalities in neurons that release GABA are thought to result in epilepsy.

2.2 Mechanisms of Neurotransmitter Release

Neurotransmitter release from synaptic vesicles is tightly regulated by calcium. It involves recycling of vesicles via the mechanisms of exocytosis and endocytosis. Specific stages of vesicle recycling include (1) reloading, (2) attachment or docking, (3) priming, (4) triggering/exocytosis, and (5) recycling/endocytosis. This section will serve as a brief overview of the process of the synaptic vesicle–recycling pathway (Fig. 3, Tab. 3).

2.2.1 Uptake of Neurotransmitters into Synaptic Vesicles

The cycle begins when synaptic vesicles take up neurotransmitter. This is accomplished using specialized neurotransmitter transporters that use ATP as an energy source. The interior of the vesicle is acidic, and an electrochemical gradient results, yielding energy for neurotransmitter

Tab. 2 Classification of neurotransmitters.

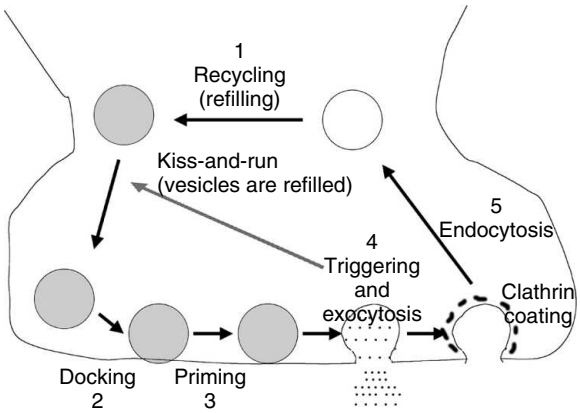

Fig. 3 Synaptic vesicle cycle. The cycle begins when synaptic vesicles take up or are filled with neurotransmitters. The ''kiss-and-run'' model does, the vesicles refill and enter the cycle.

uptake. Synaptic vesicles that are filled with neurotransmitters move to the active zone, a cytoskeletal matrix below the presynaptic plasma membrane specialized to transduce action potentials into neurotransmitter release.

2.2.2 Docking and Priming

Once at the active zone, vesicles attach to the presynaptic plasma membrane. This process is called *docking*. The vesicles contain a protein called VAMP (also called synaptobrevin, v-SNARE) that has a hydrophobic carboxyl terminus that is anchored to the membrane. VAMP forms a complex with two proteins on the plasma membrane, SNAP-25 and syntaxin (also called t-SNARES). Formation of this heterotrimeric complex, referred to as the *core complex*, causes a free energy change, which is thought to drive vesicle attachment to the membrane.

Once attached, the vesicles undergo an ATP-dependent process that primes them for calcium-dependent release. Recent studies suggest that the nsec1/Munc13 proteins mediate priming. When Munc13 is not present, no fusion-competent vesicles form, and therefore neurotransmission is blocked. Munc13 has two C2 regions, which bind calcium. It is thought that increases in diacylglycerol and calcium levels in the neuron activate Munc13 by binding to it. In addition, active zone proteins, such as RIM1, bind to Munc13 and regulate the dynamic use of neurotransmitters.

2.2.3 Triggering and Exocytosis

Calcium serves as a signal to trigger neurotransmitter release. There are three types of calcium channels in close proximity to vesicle release machinery – P/Q, N, and R – that play a role in increasing intracellular calcium to 10 to 20 μM at the active zone. Triggering occurs within 100 to 200 μs after this level of calcium is achieved. Furthermore, there must be a calcium sensor at the site of exocytosis. Recently, synaptotagmins have been identified as candidate calcium sensors. Synaptotagmin has two C2 domains that bind calcium, and electrophysiological studies have shown that

synaptotagmin is essential for only fast, calcium-triggered release.

Rab3A is a negative regulator of neurotransmitter release. Mice lacking rab3A release more neurotransmitters per calcium signal than wildtype mice. Rab3A resides on synaptic vesicles and binds to rabphilin and RIM1 in a GTP-dependent manner. Rabphilin is a soluble protein that is recruited to synaptic vesicles by rab3A. The mechanism by which these proteins work together to regulate release is still not understood.

2.2.4 Endocytosis and Vesicle Recycling

Once the vesicle is emptied of the neurotransmitter, it is endocytosed so that it may be refilled and reused. There are two main theories on how synaptic vesicles are recycled: (1) clathrin-mediated endocytosis and (2) ''kiss and run'' endocytosis. The role of a clathrin-mediated pathway is generally accepted; however, it has been proposed that a more direct pathway may predominate under certain conditions. It is thought that retrieval of the vesicle occurs by rapid closure of the fusion pore before the vesicle can collapse into the membrane. Hence, it has been termed ''kiss and run.'' Current experiments to test this model include the use of dyes, such as FM 1–43 that label vesicles, and it has been reported that dye-labeled vesicles can recycle repeatedly before losing their dye.

What is known about endocytosis is that the SNARE complex (VAMP/synaptobrevin, SNAP-25 and syntaxin) disassembles and that endocytosis is regulated by calcium. In addition, there are reports that strongly support the idea that clathrin plays an important role in synaptic vesicle endocytosis. The presence of pits coated with clathrin has been observed in nerve terminals. The number of these pits is increased when neurons are fixed at the peak of endocytic activity. Furthermore, AP-2 and AP180, clathrin adaptor complexes, are concentrated in axon terminals, and when expression of these proteins is disrupted, there is an impairment in synaptic vesicle recycling.

After endocytosis, vesicles undergo several steps before they are available for reloading. The empty vesicles acidify by proton pump activity. They then move

Tab. 3 Proteins involved in synaptic vesicle recycling.

Step	*Proteins*
Uptake of neurotransmitters	Energy-dependent transporters
Docking	VAMP or synaptobrevin (t-SNARE)
	SNAP-25 (v-SNARE)
	Syntaxin (v-SNARE)
Priming	Munc13
	RIM1
Triggering and exocytosis	Calcium channels
	Synaptotagmin
	Rab3A
	Rabphilin
Endocytosis	Clathrin
	AP-2 and AP180

back to the interior of the nerve terminal. The vesicles then fuse with early endosomes, although this step does not seem to be essential. New vesicles bud off of the early endosomes, and then, as described in Sect. 2.2.1, neurotransmitters are taken up into vesicles by active transport.

3 The Postsynaptic Component of a Synapse

3.1 The Postsynaptic Density

For the brain to function, the postsynaptic component of a synapse must be poised to respond to neurotransmitter released from the presynaptic component. In order for the postsynaptic neuron to be prepared to receive signals, the proper proteins must be localized to specific sites on the postsynaptic membrane. These sites are referred to as *postsynaptic densities* (PSDs), which are the regions of the postsynaptic membrane directly opposing the presynaptic terminal. This density may be prominent, as in the case of asymmetric (excitatory) synapses, or of the same thickness as the presynaptic membrane, as in the case of symmetric (inhibitory) synapses. Until relatively recently, the proteins and structures that compose the PSD were unknown. Through the development of biochemical and molecular techniques, much has been learned about the components of PSD in the past 15 to 20 years. Here we focus on one class of proteins found in the PSD, the neurotransmitter receptors.

3.2 Dendritic Spines

In a number of neurons, usually excitatory neurons, the dendritic tree contains dendritic spines that protrude from the main dendritic shaft. These spines are not found on inhibitory neurons. Spines increase the surface area by which neurons can receive signals. Spines come in a number of shapes and sizes, and they contain organelles, such as smooth endoplasmic reticulum, which serves as a calcium store, and polyribosomes, which allow local protein translation. Ten percent of the surface area of spines is occupied by the PSD, and this is where signaling proteins, such as receptors and effectors, are localized. Furthermore, cytoskeletal elements, such as filamentous actin, are enriched in spines.

Recent studies suggest that dendritic spines are highly plastic structures. Changes in spine numbers and shape occur in response to application of neurotrophins, hormones, and glutamate receptor agonists, such as *N*-methyl-D-aspartate (NMDA). The regulation of spine structure is thought to occur by both activity-dependent and independent mechanisms.

3.3 Excitatory Synapses: Glutamate Receptors

As discussed in Sect. 2.1.2, glutamate is the major excitatory neurotransmitter, and glutamate receptors will therefore serve as an example of excitatory neurotransmitter receptors. Postsynaptic membranes of glutamatergic synapses must contain receptors that respond to glutamate. Like many families of neurotransmitter receptors, glutamate receptors can be classified into two main groups, ionotropic and metabotropic. Ionotropic glutamate receptors are ligand-gated ion channels and include NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA), kainate, and δ receptors. Metabotropic receptors are G-protein-coupled receptors of

which a subset activates phospholipase C and phosphoinositide turnover.

3.3.1 NMDA Receptors

NMDA receptors play a role in learning and memory as well as during pathophysiological states such as ischemia or stroke. Of all of the glutamate receptors, NMDA receptors are the most tightly associated with the PSD of excitatory synapses. NMDA receptors are linked to the cytoskeleton through interactions with a scaffold of linker proteins. The cytoplasmic termini of NMDA receptor subunits are responsible for these interactions.

NMDA receptors are heteromeric and are comprised of NR1 and NR2 subunits. There are four different NR2 subunits, all of which contain C-terminal sequences of ESDV or ESEV. These sequences are consistent with the consensus sequence (S/T)X(V/I/L), which bind to protein interaction domains called PDZ domains (named for the three proteins PSD-95, Discs-large, and zona-occludens 1). In fact, these C-terminal consensus sequences found in NR2 subunits mediate their interaction with PSD-95 (also termed SAP-90), a 95-kDa protein highly enriched in the PSD. PSD-95 is a member of the membrane-associated guanylate kinase (MAGUK) protein family. PSD-95 also binds neuronal nitric oxide synthase (nNOS), linking the NMDA receptor to nNOS, thus allowing calcium influx through the NMDA receptor to activate nNOS. Furthermore, PSD-95 also binds to proteins, such as MAP1A and CRIPT, which bind microtubules, and guanylate kinase associated protein (GKAP), which binds to Shank, linking the entire complex to the actin cytoskeleton. Hence, the binding of the NMDA receptor to PSD-95 plays a role in its signaling and anchoring to the cytoskeleton.

It appears that the binding of NMDA receptors to PSD-95 is not important in mediating its localization to the PSD. In fact, elimination of PSD-95 in mice by knockout technology did not result in a decrease in synaptic localization of NMDA receptors at the PSD. However, it could be argued that other MAGUK proteins could be involved in NMDA receptor localization, and recent reports suggest that this indeed could be the case.

The NR1 subunit also plays an important role in the localization of the NMDA receptors to the PSD. NR1 subunits have alternative splice variants of their carboxyl termini; however, a membrane proximal segment, termed C0, is common to all NR1 subunits. This C0 segment interacts with α-actinin, a protein that interacts with F-actin. Some splice variants of the NMDA receptor also contain a C1 exon segment in the carboxyl region that binds to neurofilament. Finally the cytosolic regions of both NR1 and NR2 subunits bind spectrin, an actin-binding protein. Thus, the NMDA receptor is tightly associated with the PSD and cytoskeleton via interaction with proteins that associate with microtubules and actin.

3.3.2 AMPA Receptors

Although not as tightly associated with the PSD, AMPA receptors are also concentrated at the PSD of excitatory synapses. Many synapses contain NMDA receptors but not AMPA receptors, especially early in development. These synapses are termed *silent synapses* because depolarization of the membrane by AMPA receptor function is often necessary for NMDA receptors to become functional themselves. Electrical activity can regulate the delivery of AMPA

receptors to the PSD, and it is thought that this may be an underlying mechanism for learning and memory.

AMPA receptors are heteromers of GluR1-4 subunits. Like NMDA receptors, the carboxyl termini of AMPA receptors interact with intracellular proteins, some of which are PDZ-containing proteins. However, most of these PDZ-containing proteins are different than those that bind NMDA receptors. Two multi-PDZ proteins that interact with GluR2 and GluR3 have been identified, ABP (for AMPA receptor binding protein) and GRIP (for glutamate receptor interacting protein). However, the function of the binding of these proteins to GluR2 and 3 is still not completely clear. Similarly, GluR2 and 3 have been shown to interact with the PDZ-containing protein PICK1 (protein that interacts with C-kinase 1), and it is thought that this interaction plays a role in linking AMPA receptors to protein kinase C.

Recent evidence suggests that PSD-95 plays a role in localizing AMPA receptors to synapses. PSD-95 also binds a protein called *stargazin*, and it has been shown that the concurrent binding of AMPA receptors and stargazin to PSD-95 is important for the delivery of AMPA receptors to the PSD. Thus, MAGUK proteins may play a role in the delivery of multiple receptors, such as NMDA and AMPA receptors, to the synapse.

Another family of PDZ-containing proteins, the LIN-10/Mint1-3 family, has been shown to play a role in regulating surface expression of AMPA receptors. The mechanism by which this family of proteins regulates receptor targeting is currently unknown.

3.3.3 Kainate and δ Receptors

Kainate receptors can be pre- or postsynaptic, and consist of heteromers of GluR5-7, KA1, and KA2 subunits. Like NMDA and AMPA receptor subunits, the GluR6 and KA2 subunits can bind to PSD-95. GluR6 binds to the first PDZ domain of PSD-95 and KA2 binds to the SH3 and GK domains. PSD-95 may serve to localize kainate receptors to the PSD; however, this has not yet been definitively shown. δ receptors are comprised of GluRδ subunits, of which GluRδ2 has been shown to bind to the PSD-95/MAGUK family member PSD-3/chapsyn-110. This interaction is thought to anchor GluRδ receptors to the PSD.

3.3.4 Metabotropic Glutamate Receptors

Metabotropic glutamate receptors are classified into three main groups: group 1 (includes mGluR1 and 5) activate phospholipase C, group 2 (includes mGluR2 and 3) and group 3 (includes mGluR4, 6, 7, and 8), both of which inhibit adenylate cyclase. Similar to the ionotropic glutamate receptors, mGluR targeting is mediated by the binding of intracellular carboxyl termini to intracellular partners.

mGluRs of group 1 are concentrated in a ring around the PSD. Recent studies have focused on the role of their binding partners in localization and signaling. It appears that these receptors bind to Homer via a PPXXF motif present in the carboxyl terminus. A subset of Homer proteins multimerize and are thought to crosslink group 1 mGluRs to other mGluRs or to other proteins containing Homer binding motifs, such as the IP_3 receptor. It is thought that the binding of Homer to mGluR1 and 5 is similar to the binding of PSD-95 to NMDA receptors in that it scaffolds the receptor with signaling proteins.

The carboxyl terminal tail of mGluR5 also contains a PDZ-binding motif. As

such, mGluR5 has been shown to bind to the PDZ domain of Shank. Since Shank binds to actin, this interaction may serve to anchor the mGluR5 to the PSD cytoskeleton. Since Shank is part of the NMDA receptor complex, it may serve to aid in crosstalk between NMDA and metabotropic glutamate receptors.

3.4 Inhibitory Synapses: GABA Receptors

The principal inhibitory receptor in the brain is the ionotropic GABA receptor, which is a class of ligand-gated ion channels made of subunits from at least six different types. GABA receptors are primarily found at the PSD of inhibitory synapses with a small subset found in extrasynaptic locations. Like the glutamate receptors, GABA receptors rely on interaction with intracellular proteins to help to anchor it at the PSD. However, unlike NMDA and AMPA receptors, GABA receptors interact with partners via their intracellular loops between transmembrane regions 3 and 4.

3.4.1 $GABA_A$ Receptors

Ionotropic $GABA_A$ receptors are found throughout the mammalian CNS. Activation of this receptor results in increased chloride conductance of neuronal membranes, which can be blocked by bicuculline. $GABA_A$ receptors are pentamers, and there are at least seven classes of $GABA_A$ receptor subunits – α, β, γ, δ, ε, π, and θ. The most common $GABA_A$ receptor in the mammalian CNS consists of two copies each of $\alpha 1$ and $\beta 2$ subunits associated with a $\gamma 2$ subunit. Benzodiazapines bind with high affinity to a subset of $GABA_A$ receptors, where they exert their sedative and anticonvulsive effects. Furthermore, barbiturates interact with $GABA_A$ receptors.

A $GABA_A$ receptor-associated protein (GABARAP) has been identified, and this protein binds to the intracellular loop. GABARAP has 30% identity with a light chain of some microtubule-associated proteins, suggesting that GABARAP may associate with microtubules. Indeed, GABARAP fractionates with microtubules. Thus, $GABA_A$ receptors are linked to the cytoskeleton of the PSD at inhibitory synapses.

3.4.2 $GABA_B$ Receptors

$GABA_B$ receptors are metabotropic receptors that inhibit adenylate cyclase activity and intracellular calcium levels. They are widely expressed throughout the mammalian CNS. They are heterodimers of $GABA_{B1}$ and $GABA_{B2}$ subunits, which interact through their carboxyl termini. $GABA_B$ receptors are the target of baclofen, which is used to treat spasticity. Thus, $GABA_B$ receptors may be a treatment for disorders such as epilepsy.

3.4.3 $GABA_C$ Receptors

Like the $GABA_A$ receptors, $GABA_C$ receptors are ligand-gated chloride channels. However, unlike $GABA_A$ receptors, $GABA_C$ receptors are not blocked by bicuculline and do not bind benzodiazepines. $GABA_C$ receptors contain ρ subunits of which two types (1 and 2) can be assembled into homomeric or heteromeric pentamers. These receptors play an important inhibitory role in the retina. MAP1B (microtubule associated protein 1B) binds to $GABA_C$ receptors, anchoring it to the neuronal cytoskeleton.

4
Changes in Neuronal Morphology in Response to Signals

4.1
Signals that Regulate Dendrite Patterning

4.1.1 Electrical Activity

Electrical activity plays a role in shaping synaptic connections in the nervous system during development as well as during experience and learning. It is thought that signals from incoming presynaptic terminals activate the appropriate postsynaptic partners, shaping the dendritic tree so that it will have the correct mature morphology. Recent evidence suggests that activity also "fine-tunes" already branched dendrites.

Blocking activity can result in decreased dendritic growth and branching. This has been demonstrated in the visual system where dark-rearing results in attenuation of the length and number of dendritic branches in stellate and lateral geniculate neurons. In the cerebellum, when granule cells fail to innervate Purkinje cells, their dendritic branches are less elaborate. Similarly, when cultured sympathetic or hippocampal neurons are depolarized using KCl, dendritic branching increases.

What do these results mean physiologically? When rats are reared in enriched environments, the dendritic arbors of cortical pyramidal cells are much more complex than those of rats reared in control environments. Furthermore, it has been shown that in some systems, activity does not affect dendritic arborization. Recently, a study of the dynamics of dendrite development in the optic tectum of frogs provided insight into apparent conflicts regarding whether activity is an important factor in determining dendrite morphology. It appears that there is a specific developmental time window ("critical period") when dendrite patterning can be regulated by electrical activity. Hence, for neurons that are plastic for a critical period during development, activity may influence dendrite number only during this critical period. For neurons that remain plastic into adulthood, for example in the hippocampus and cortex, activity (perhaps as a result of environment) may continue to shape the dendritic tree.

4.1.2 Neurotrophins

Originally, the neurotrophins (nerve growth factor or NGF, brain-derived growth factor or BDNF, Neurotrophin-3 or NT-3, and neurotrophin-4 or NT-4) were studied as survival factors for neurons. However, in the late 1980s, it was found that neurotrophins could regulate dendritic patterning in the peripheral nervous system. Similarly, soon after, it was discovered that neurotrophins could also regulate dendrite patterning in the developing neocortex. In recent years, BDNF has been shown to promote dendritic arborization in the developing retina and cerebellum and as a mediator of activity-dependent synaptic plasticity.

4.1.3 Extracellular Signaling Proteins

Although little is known about signaling molecules that play a role in dendrite patterning, studies performed during the past five years have led to the identification of proteins that regulate dendrite branching (Fig. 4). Semaphorin 3A, originally identified as a chemorepellent for cortical axons, acts to regulate dendrite patterning in these same neurons by acting as a chemoattractant for apical dendrites. Similarly, the ephrin family of ligands and receptors was originally identified as an axon guidance molecule in the visual system. Overexpression of one of the ephrin

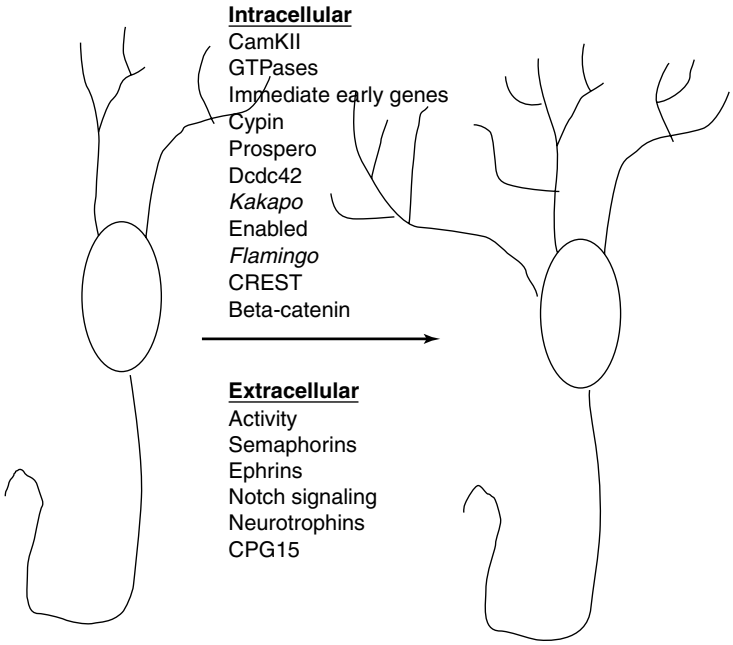

Fig. 4 Signaling proteins that regulate dendrite branching and morphology.

receptors, EphA3, results in decreased dendrite branching in the visual system. Recent studies have shown that other proteins, such as Notch, Wnt, beta-catenin, and the cell adhesion molecule L1, also regulate dendrite growth. Like EphA3, Notch is a receptor, and increasing amounts of Notch result in decreased dendritic growth. In contrast, but in parallel with Semaphorin 3A, L1 signaling positively affects dendrite number. Thus, it appears that regulators of axonal pathfinding also play a role in dendritic patterning (Fig. 4).

In addition to axon guidance molecules, hormones regulate dendritic arborization. Rats that have underactive thyroid glands have attenuated dendrite arborization while those with overactive thyroids have more complex arborization in hippocampal pyramidal neurons. Similarly, thyroid hormone increases dendritic arbors in neonatal rats, while estradiol increases dendrite number, and exposure to glucocorticoids decreases dendrite number. Thus, hormones may play an ongoing role in determining dendrite morphology.

4.1.4 Intracellular Signaling Molecules

The study of intracellular molecules that play a role in dendrite patterning is a relatively new field. However, recent studies indicate that intracellular regulators of dendrite arborization include calcium/calmodulin-dependent protein kinase II (CaMKII), the small GTPases, immediate early genes, cypin, and a number of novel genes (Fig. 4). The role of CaMKII in dendrite patterning has been studied in *Xenopus* tectal neurons. CaMKII negatively regulates dendritic growth and is thought to be a signal that halts growth. The role of small GTPases, including Rho, Rac, and Cdc42, appears to be more complex. These proteins regulate

the actin cytoskeleton, and together, they mediate the effects of extracellular signals. Similarly, activity increases the expression of immediate early genes, two of which are *Arc* (for activity regulated cytoskeletal-associated protein) and *Narp* (for neuronal activity-regulated pentraxin). Although there is no direct evidence that *Arc* mediates dendritic remodeling, its localization in dendrites makes it a prime candidate as an intracellular mediator. Stronger evidence exists for a role for *Narp* in dendrite patterning. *Narp* is induced by electrical activity, is secreted from neurons, and stimulates dendritic growth in cultured neurons. Cypin (for cytosolic PSD-95 interactor) is another protein that is upregulated by electrical activity. Cypin is a guanine deaminase that binds to tubulin heterodimers and promotes microtubule assembly. Cypin's enzymatic activity may play a role in dendrite patterning since its overexpression results in increased dendrite number. Moreover, knocking down cypin protein levels results in a decrease in dendrite number.

Genetic screens are underway to identify genes that control dendrite morphology. *Drosophila* screens have identified at least a dozen candidates that regulate sensory neuron dendrite patterning. These include the transcription factor Prospero, genes that regulate the cytoskeleton such as Dcdc42, *kakapo*, and enabled, and the membrane-spanning protein *flamingo*. Using a strategy called *transactivator trapping*, a calcium-responsive transactivator called CREST was very recently identified. CREST plays a role in dendritic patterning in the mammalian hippocampus and cortex. Mice with disrupted expression of CREST have deficits in calcium-dependent dendritic growth. Thus, the field of dendrite patterning is quickly evolving with the identification of new players that regulate dendrite number and morphology.

4.2 Signals that Regulate Axons

4.2.1 Electrical Activity

The role of electrical activity on the patterning of the visual system has been well studied. Dark-rearing or visual deprivation during visual system development results in a disruption of ocular dominance columns in layer 4 of the cortex. Similarly, if action potentials are blocked during the "critical period" when thalamic axons grow into the primary visual cortex, normal branching patterns of these axons are disrupted. Furthermore, the neurons project into areas where they normally do not innervate. Similarly, in barn owls, the auditory map is guided by vision, and hence electrical activity. If the owls are raised wearing prismatic spectacles that displace vision, their auditory neurons become tuned to sound locations that correspond to visually displaced sites. Thus, neuronal activity plays a major role in guiding axons in the visual and auditory systems (Fig. 5).

The role of electrical activity on axon guidance has been recently studied using cultured Xenopus spinal neurons. Brief periods of electrical stimulation increase netrin-1 induced attraction and converts myelin-associated glycoprotein repulsion to attraction. In contrast, electrical activity does not play a major role in axon guidance in mammalian motor neurons. Thus, electrical activity may serve as a modulator for axon guidance in particular sets of neurons.

4.2.2 Extracellular Cues: Netrins

It has been long established that neuronal migration and pathfinding is regulated

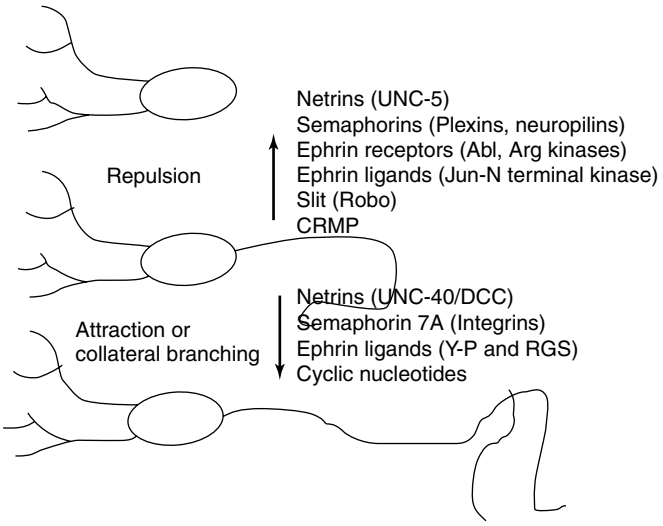

Fig. 5 Signaling proteins involved in axon guidance. This is a very simplified view of proteins that regulate axon attraction or repulsion. There is still much that is not known. Y-P is tyrosine phosphorylation and RGS is regulator of G-protein signaling. All other names are discussed in more detail in the text.

by extracellular cues. These cues include the netrins, semaphorins, ephrins, and Slits (Fig. 5). Netrins were first identified as playing a role in axon guidance in both the vertebrate and invertebrate nervous systems. They are diffusible substances, and the same netrin that can be attractive to some axons may be repulsive to others. Netrins bind to two classes of receptors UNC-40 and UNC-5. Netrin attraction appears to involve UNC-40 homologs (i.e. deleted in colorectal cancer, DCC), which signal through phospholipase C, mitogen-activated kinase, and the small GTPases Cdc42 and Rac. Repulsion appears to be mediated by UNC-5 family members either in combination with UNC-40 homologs (DCC) or alone. The cytosolic regions of UNC-5 homologs contain protein interaction domains, which may regulate intracellular signaling.

In addition to providing cues for axon pathfinding, netrins can also promote axon outgrowth. The nuclear factor of activated T cell (NFAT) transcription factors act downstream of DCC. Inhibition of NFAT activation or elimination of NFAT in mice results in defects in axonal outgrowth.

4.2.3 Extracellular Cues: Semaphorins

Some members of the semaphorin family are membrane-bound, and some are secreted. In *Drosophila*, the invertebrate semaphorin SemI was identified in genetic studies of axon fasciculation. In vertebrates, semaphorins were discovered in assays of growth cone collapse. Sema3A is a repulsive cue for NGF-responsive neurons of the dorsal root ganglia and is thought to prevent axons of these neurons from invading the ventral spinal cord during development. Plexins and neuropilins have been identified as receptors for the semaphorins. Neuropilins can associate with plexins and form functional receptors

for Semaphorin 3A. Met, a receptor tyrosine kinase, forms a complex with one of the plexins (B-1), signaling through small GTPases to alter actin dynamics, which then results in axonal repulsion. In contrast, a different plexin subtype (A-1) signals through a cytosolic protein called *collapsin response mediator protein*(CRMP). Recently, it has been shown that overexpression of CRMP results in multiple axon formation. CRMP binds to tubulin heterodimers and promotes microtubule assembly, a mechanism, which may underlie CRMP's role in axon guidance and outgrowth.

In contrast to Sema3A, the plexins, which primarily cause axon retraction or repulsion, semaphorin 7A (Sema7A) has been shown to promote axon outgrowth. In fact, Sema7A does not signal through neuropilins or plexins; it binds to integrins instead. Its signaling is mediated by mitogen-activated and focal adhesion kinases.

4.2.4 Extracellular Cues: Ephrins

It is thought that complementary expression and binding of ephrin receptors in retina to their ephrin ligands in tectal targets mediate retinal–tectal patterning. Unlike other axon guidance molecules, ephrins are not secreted. Ephrins of type A are GPI-linked and ephrins of type B are transmembrane proteins. Ephrin receptors for both types of ligands are transmembrane receptors with intracellular tyrosine kinase domains. Like other tyrosine kinase receptors, binding of Eph ligands to their receptors results in receptor phosphorylation and dimerization. Activation of these receptors results in inactivation of Ras and suppression of extracellular signal-regulated kinase (ERK). Furthermore, signaling of ephrin receptors through Abelson (Abl) and related (Arg) kinases results in axonal repulsion. In addition, the ephrin ligands themselves can be involved in reverse signaling. There are three possible pathways: (1) one involving tyrosine phosphorylation, (2) one involving Jun-N terminal kinase, and (3) one involving the regulator of G-protein signaling, inhibiting G-protein coupled receptor signaling. The first and third pathways are involved in axonal outgrowth, and the second pathway is involved in axonal repulsion (Fig. 5).

4.2.5 Extracellular Cues: Slits

Slit was originally identified in a genetic screen in *Drosophila* designed to identify proteins involved in embryonic patterning. More recently, it has been shown that both *Drosophila* and vertebrate slits are axon repellents. Roundabout (Robo) is the receptor that is responsible for the actions of slit (Fig. 5). Although potential players have been identified, genetic studies have shown that slit signaling is complex, and no concrete evidence exists to assign a definitive signaling pathway for slit in axonal repulsion. However, like the ephrin receptor signaling, Abl may play a role in Robo-mediated slit signaling. Enabled, an Abl substrate, and Capulet, an adenylate cyclase-associated protein, act downstream of Abl. There is evidence that small GTPases play a role in mediating slit-promoted axon repulsion. Furthermore, it is thought that slit can use DCC as a receptor in its signaling.

4.2.6 Extracellular Cues: CPG15

CPG15 is an extracellular molecule that is anchored to the plasma membrane by a glycosyl–phosphatidylinositol linkage. CPG15 mRNA is expressed during development, and the protein is expressed in areas of the brain that are developmentally

plastic, such as in the visual system. CPG15 mRNA is upregulated by electrical activity and BDNF and is responsible for regulating the growth of apposing dendritic and axonal arbors by decreasing rates of branch retractions of presynaptic retinal axons. It is still not known what protein functions as the CPG15 receptor.

4.3 Intracellular Signaling Molecules

CRMP, discussed above as a mediator of semaphoring signaling, causes the formation of multiple axons when overexpressed (Fig. 5). In addition, CRMP is present at high levels in axonal growth cones, and thus, may play a major role in determining neuronal morphology. Other intracellular signaling molecules that can regulate axon morphology include cyclic nucleotides, which convert repulsive growth cone responses to attractive ones, and calcium, which can regulate growth cone turning, and hence, axonal guidance (Fig. 5). It is clear that we are just beginning to make headway into understanding the mechanisms by which axonal morphology is determined.

5 Perspectives

Our understanding of how the brain functions is expanding exponentially. Recent advances have resulted in our understanding of how neurotransmitter vesicles are recycled, how signaling complexes are targeted to synaptic sites, and how neuronal morphology is determined. New molecular and biochemical methods will enable us to continue to identify and clarify details and mechanisms underlying neuronal function. This chapter is intended to build a basic foundation in neuron chemistry and to provide the background necessary to understand ongoing investigations of mechanisms that are critical for neuronal signaling.

Keywords

Invertebrate
An animal that lacks an internal skeleton and maintains body integrity by a variety of strategies including hydrostatic pressure or a rigid exoskeleton.

Mention of trade names or commercial products in this publication is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the US Department of Agriculture.

Neuropeptide
This is a generic term for a peptide of as few as 3 to nearly 200 amino acids, produced in specialized neurons, released from neurosecretory cells and usually acting as a hormone.

Neurosecretion
This is the release of material (e.g. biogenic amines, peptides) from secretory granules located in neurosecretory cells in response to internal or external stimuli.

Precursor
Neuropeptides are typically synthesized as members of a large precursor polypeptide that is processed by specialized proteases and other enzymes resulting in production of biologically active peptides.

Receptor
Receptors are signal transduction proteins embedded in cell membranes that bind ligands (e.g. neuropeptides) and transmit signals from the exterior to the cytoplasm. Neuropeptide receptors are typically associated with G-proteins that bind guanine nucleotides and are referred to as GPCRs or G-protein coupled receptors.

Invertebrates present enormous diversity and occupy every ecological niche. They comprise microscopic worms and large squid, sedentary corals and migrating locusts. The 30 invertebrate phyla include animals with the relatively simple nerve net of the cnidarians and the complex central and peripheral nervous systems of insects and molluscs. Common to all invertebrates, regardless of size, habit or complexity, however, is a dependence upon neuropeptides for control of physiological processes. This feature is shared among all animals. Activities ranging from behavior and reproduction to energy metabolism and metamorphosis are under the control of one or more neuropeptides. The lower invertebrates appear to rely upon few families of neuropeptides that include large numbers of a variety of sequences, whereas higher invertebrates have many neuropeptide families with fewer numbers of different sequences within each family. In both cases, however, there is a complex neuropeptide biochemistry. Mechanisms of neuropeptide synthesis, secretion, action, and catabolism are similar to those described for vertebrates, but useful differences exist. These differences facilitate studies of biochemical evolution and provide unique experimental systems. It was, in fact, work on insect metamorphosis early in the twentieth century that led to the concept of neurosecretion. Research into invertebrate neuropeptides is as important to better understand the life processes of animals, in general, as it is to discover environmentally responsible means to control pests.

1 Background

1.1 Neurosecretion

Neurosecretion is the release of signal molecules – peptides, amines, or both – from specialized cells. The molecules effect specific responses after binding to receptors on the target cell. Molecules acting at a target in close proximity to the release site (e.g. from the efferent end of one neuron to the afferent end of the adjoining neuron, or at the membrane of an innervated cell) are considered neurotransmitters. If the release and target sites are distant from one another, then the signal molecule acts as a hormone. *Neuropeptide* is a generic term for regulatory peptides, as short as 3 to nearly 200 amino acids, secreted from neural cells, which act as neurohormones or neurotransmitters. They are produced in specialized neurons, stored in secretory granules and released in response to internal or external stimuli. Invertebrates use an enormous number and variety of neuropeptides to control most physiological processes.

One of the earliest demonstrations that factors from one tissue may affect other tissues not neurally connected was work by Berthold (1849) on castration in roosters. Baylis & Starling (1902) noted that material secreted from the small intestine of dogs stimulated pancreatic activity. They called the active factor *secretin* and coined the term *hormone*. However, neither the testes nor the intestines are neural organs, and it was actually research on an insect that experimentally demonstrated the merging of neural and endocrine activities. Kopec performed ligation and surgical experiments on the larvae of the gypsy moth *Lymantria dispar*, noting that the brain was required for larval development and molting. After further work, he concluded that the brain must be an organ of internal secretion. This was the first report that a neural organ could also act as an endocrine organ. During the same period, Banting & Best made their landmark discovery of insulin and Spiedel identified secretory cells within the spinal kord of skates.

Secretion of hormones by neural tissues is now a principle of neurobiology. The idea that neural tissues also function as endocrine tissues, however, was a point of scientific controversy when proposed in the early 1900s, and many decades would pass before wide acceptance of the neuroendocrine concept. Initial opposition to a revolutionary idea, from work on an invertebrate, eventually gave way to experimental proof from scores of laboratories, and the importance of neuropeptides as key messengers of neurosecretion was recognized.

Invertebrates comprise at least 30 phyla, two of which, Nematoda and Arthropoda, include most of the different animal species known. Neuropeptides are frequently members of families of related sequences, which provide biological variability, redundancy, and an enormously complex picture for the investigator. A complete cataloging of invertebrate neuropeptides and their actions is impractical and not of particular value to an introductory review. Rather, consideration of selected neuropeptides and their functions in representative phyla will be used to illustrate the complex and pervasive action of these molecules throughout the invertebrates.

1.2 Neuropeptides

Neuropeptides are synthesized as large inactive precursors, preproneuropeptides,

that are transported within the cell from the polysome, through the rough endoplasmic reticulum (RER), and on to the Golgi where processing takes place. An N-terminal hydrophobic leader sequence guides translocation through the RER membrane and is removed by an endoproteolytic signal peptidase. The proneuropeptide is transported along the ER to vesicles within the Golgi. Packaged with the proneuropeptide in the vesicle are processing enzymes, including both proteases and nonproteases, required for generation of active neuropeptide, ready for secretion. The processing of all propeptides is similar. Active peptide sequences within precursors are typically flanked by basic amino acids (e.g. K and/or R), which serve as primary cleavage signals for propeptide convertases (or proconvertases). Proconvertases are members of a family of subtilisin-like endoproteases. Those that process neuropeptides are specifically able to function in the acidic environment of the neurosecretory cell vesicle. After proconvertase action, carboxypeptidases trim the C-terminus. Many neuropeptides in invertebrates are further modified at the C-terminus, N-terminus, or both, to protect them against degradation by cellular proteases during transport to target receptors. Amidation requires a C-terminal G, which is converted to an amide by peptidylglycine α-amidating monooxygenase (PAM). PAM is a bifunctional enzyme that has both peptidylglycine α-hydroxylating monooxygenase (PHM) and peptidyl-α-hydroxyglycine α-amidating lyase (PHL) domains. In some invertebrates, amidation is done by separate PHL and PHM enzymes. At the N-terminus, a glutamic acid (E) residue is converted by glutaminyl cyclase into pyroglutamic acid (pE). Peptide processing is a generally conserved system among animals and between different tissues, but specific variations in enzyme complement provide flexibility in processing, depending, for example, upon the tissue or developmental stage requirements. In lower invertebrates, some additional processing proteases that recognize acidic rather than basic residue cleavage sites have been proposed.

2 Invertebrates

2.1 Cnidarians

The most primitive of the animals to have a nervous system are in the phylum Cnidaria, which includes classes Hydrozoa (*Hydra*), Scyphozoa and Cubozoa (jellyfishes), and Anthozoa (corals, anemones). Development of the Hydrozoa and Anthozoa is particularly well studied. The cnidarian nervous system is a simple nerve net lacking the arborization found in higher invertebrates. Nevertheless, the cnidarian nervous system and its control are biochemically quite complex. The chemical messengers seem to be nearly all peptides. In fact, typical neurotransmitters such as acetylcholine, catecholamines, and serotonin have not been found, and the nervous system is primarily peptidergic.

The *Hydra*, a small freshwater polyp known for its ability to regenerate a complete organism from a few cells, can be manipulated to produce a complete epithelial self devoid of a nervous system. Addition of a few neuronal stem cells results in the production of a normal, functioning nervous system. This remarkable plasticity is due to the action of regulatory peptides. In addition, the neurons of cnidarians are multifunctional, serving the

roles of sensory neurons, interneurons, motor neurons, and secretory neurons; roles fulfilled separately among the more specialized neural cells of higher animals. It may not be surprising that of all regulatory peptides in *Hydra*, 50% are believed to be neuropeptides.

Over 800 peptides have been isolated from *Hydra* through the Hydra Peptide Project and about 260 have been sequenced. Although many of the peptides are present in other organisms, many appear to be unique to *Hydra*. At least 60 unique neuropeptide sequences have been reported for anemones. Most cnidarian neuropeptides are approximately 3 to 10 residues long, amidated at the C-terminus and blocked by pE at N-terminus. In addition, the C-terminal sequences usually include a penultimate Arg (R) residue. Thus, groups of cnidarian neuropeptides are known as *RFamides*, *RNamides*, *RPamides*, *RWamides*, and so on, depending upon the terminal residue. All the RXamides have neuromuscular effects.

Although the *RXamide* structure predominates, other sequences are present. Among them are EQPGLWamide, known as metamorphosin A, isolated from the anemone *Anthopleura elegantissima* and Hym-355 (FPQSFLPRGamide) from *Hydra magnapapillata*. Metamorphosin A stimulates hydrazoan metamorphosis, and Hym-355 stimulates neuron differentiation. Analogs of vertebrate gonadotropin-releasing peptide hormones are also present in cnidarians. Thus, cnidarians have numerous neuropeptides that affect neuromuscular activity such as feeding but also have neuropeptides involved in controlling development.

Genes for many cnidarian neuropeptides have been cloned. One notable feature is the high copy number of peptides encoded within some genes. For example, in the sea pansy *Renilla kollikeri*, the precursor of the peptide pEGRFamide contains 36 copies of this peptide sequence and up to 38 copies of peptides have been observed in genes from *A. elegantissima*. These are some of the highest copy numbers reported for neuropeptides, and suggest highly efficient production of certain sequences. There are other cnidarian neuropeptide genes that code for fewer and for single copies of some peptides, and genes that code for more than one different peptide.

Another feature of cnidarian neuropeptide genes is that they code for cleavage sites in precursors that are bounded by acidic residues. This is in addition to the typical basic and dibasic cleavage site residues found in peptide precursors. To accommodate these unusual acidic cleavage sites, additional processing enzymes have been proposed including endoproteases, aminopeptidases, and a dipeptidyl aminopeptidase. Cnidarians appear to require neuropeptides for all neural transmission and for developmental signaling as well. They depend upon an efficient production system that features large copy numbers of active sequences in precursors and a processing pathway that includes proteases that recognize atypical processing sites. The relatively simple nervous system of cnidarians is biochemically highly complex. In this phylum housing the invertebrates with the most primitive of nervous systems, both the number of neuropeptides and their involvement in a variety of complex biochemical events illustrate that primitive is not simple.

2.2 Platyhelminthes

Flatworms comprise over 13 000 species, 10 000 of which are parasitic to animals.

The platyhelminth phylum comprises four classes. Turbellarians are free-living and aquatic (e.g. *Planaria*), Monogenea that includes ectoparasites of fish and reptiles, Trematoda including endoparasites of vertebrates (e.g. *Schistosoma*), and the Cestodes (tapeworms). Flatworms range in size from the microscopic up to 30-m long tapeworms, and represent the early appearance of bilateral metazoans. Their nervous systems are ladderlike, with central and peripheral components, and unlike the cnidaria have a rudimentary brain.

Most of the information on platyhelminth neuropeptides has been obtained by immunoscreening, and immunoreactivity has been detected throughout the flatworm body including sense and reproductive organs, and alimentary tissues. However, few neuropeptides have been isolated and characterized. The six sequences available are members of two neuropeptide families. Two neuropeptide F sequences are analogous to the vertebrate neuropeptide Y, have conserved proline (P) residues in the N-terminal region of the peptides and characteristic *x*-R-*x*-R-*y*-amide C-terminal motifs. The *y* is a phenylalanine (F) in flatworm NPFs and a tyrosine (Y) in NPY.

The second family represented is the FMRFamides (more generally known as FaRPs for FMRFamide-related peptides). Four flatworm sequences are characterized from four species. YIRFamide, GYIRFamide, and RYIRFamide were isolated from nonparasitic turbellarians and GNFFRFamide was isolated from the parasitic cestode tapeworm *Moniezia expansa*. The invertebrate homolog, neuropeptide F, was first isolated from *M. expansa* and is expressed abundantly and widely within this animal. There is no gene information available for platyhelminth FMRFamides, but the presence of amidated C-terminals in all isolated sequences and precedent from lower and higher phyla suggest that processing should resemble the mechanisms found in other animals. A gene for *M. expansa* NPF has been characterized, it is highly expressed and codes for a single peptide. A cDNA containing the gene coding for PAM has been isolated from the parasitic trematode *Schistosoma mansoni*, and the expressed *S. mansoni* enzyme has different kinetics from vertebrate PAM.

2.3 Nematodes

Nematodes are unsegmented roundworms with longitudinal nerve chords and a nerve ring. The anatomy of the nervous system is no more complex than the platyhelminths but a greater number of distinct organs is present including mouthparts with a pharyngeal pump to facilitate feeding, an intestine that serves as a metabolic organ somewhat analogous to the liver, gonads, and sexually dimorphic features. Most nematodes are microscopic, but some species are quite large, measuring in meters. As a group, nematodes are second only to the insects in number of species, breadth of distribution, and amount of biomass. They occupy nearly every ecological niche and include both parasitic and nonparasitic species.

Parasitic nematodes infect vertebrates, invertebrates, and plants. Their importance to medicine and agriculture has made them subjects of extensive research efforts to discover ways to effectively control them. A nonparasitic free-living nematode *Caenorhabditis elegans* has become important as a molecular genetic model and tool for discovery of cellular mechanisms in both vertebrates and invertebrates. In fact, the *C. elegans*

genome was the first animal genome to be completely sequenced.

The neuropeptides predominantly studied in nematodes are members of the FaRP family of sequences. The neuromuscular effects of these peptides have made them a focus of veterinary medical research to discover treatments for parasitic disease of livestock, and the discovery of large numbers of FaRP genes in *C. elegans* has captured the attention of molecular biologists. Two species, then, have predominated nematode neuropeptide research: *Ascaris suum*, an important parasite of livestock, and the molecular model *C. elegans*.

The first neuropeptide isolated from a nematode was the FaRP KNEFIRFamide from *A. suum*, and the first FaRP gene cloned from nematodes was from *C. elegans*. To date, in fact, all neuropeptides isolated from nematodes have been FaRPs. These include 19 different sequences from *A. suum*, 1 FaRP from another animal-parasitic nematode, *Haemonchus contortus*, 5 from the free-living species *Panagrellus redivivus*, and 1 from *C. elegans*. Nematode FaRP genes contain coding sequences that predict large numbers of FaRP sequences. *C. elegans* has 22 FaRP-like peptide genes (*flp* genes) coding for approximately 60 different FaRP sequences, the plant-parasitic nematode *Globodera pallida* has 5 *gpflp* genes coding for 14 different sequences, and a gene cloned from *A. suum* (*afp-1*) codes for 6 different sequences. Around 70 different FaRPs have been identified in nematodes, with only a minority having been tested physiologically, usually in a muscle assay system using *A. suum*. All have neuromuscular effects, but not all of the effects are the same, leading to the hypothesis that a variety of FaRP receptors exist. This argument is supported by the large number of unique sequences identified.

Some intriguing questions arise from a survey of FaRP sequences in nematodes. In *C. elegans*, many of the *flp* genes are expressed throughout development. Nematodes have an egg stage, four larval stages, and adults. *C. elegans flp*s 1 to 12 are expressed in all 6 stages but *flp*s 8, 9, and 13 are expressed only during the egg and larval stages and not in the adult stage. This suggests developmental involvement of at least some FaRPs.

Among the many sequences identified in nematodes, KHEYLRFamide is present in all species examined and is the most abundant FaRP in *A. suum, H. contortus, C. elegans* and *P. redivivus*. In both *C. elegans* and *G. pallida,* the genes coding for KHEYLRFamide also code for multiple copies of the peptide. A second FaRP KSAYMRFamide is present in *A. suum, G. pallida, C. elegans* and *P. redivivus*, and the genes in *C. elegans* and *G. pallida* also code for multiple copies of this FaRP. The abundance of these two sequences and their appearance in all nematodes suggests that they have some fundamental importance to all species.

In concert with this shared importance, the wide variety of unique sequences observed suggests some species-specific or developmental stage-specific roles. In addition, it is interesting to note that among the complex variety of nematode FaRPs, only two (above), are widely shared and most FaRPs have been identified in either parasitic or nonparasitic species, but not both. Examples include SADPNFLRFamide and SDPNFLRFamide, which are present only in the free-living species *C. elegans* and *P. redivivus*, and AVPGVLRFamide, which is exclusive to the animal – (*A. suum*) and plant – (*G. pallida*) parasitic nematodes.

Can FaRP cocktails be used to sort nematode species for phylogenetic comparison?

Are there really a few *universal* FaRPs in nematodes? What are their functions among different species? Are there FaRPs associated with parasitism? As more species are examined, such questions may be answered. Levels of specific FaRPs in *C. elegans* can affect feeding and social behavior, and may also influence activation of specific receptors. FaRPs, then, do not solely affect neuromuscular activity.

Not all nematode neuropeptides are FaRPs. Immunochemical screens using antisera against vertebrate and invertebrate antigens provide circumstantial evidence for numerous other neuropeptides in nematodes. At least one report showed that *Ascaris* homogenates elicit responses in insects similar to those associated with the insect metabolic neuropeptide adipokinetic hormone. More directly, a screen of the *C. elegans* genome has revealed over 30 non-*flp* genes encoding more than 50 putative neuropeptides. Thus, nematodes must depend upon a large number and complex variety of neuropeptides for physiological regulation, and most have yet to be examined.

2.4 Arthropods

Studies of neuropeptides in arthropods constitute a much more comprehensive approach than in the lower invertebrates. Well-defined organs with specific physiological functions, a sophisticated nervous system, and physical size of many arthropods facilitate investigations with a variety of biochemical, physiological, molecular biological, and anatomical methods. This is especially true in the insects, where many families of neuropeptides have been discovered, and where member neuropeptides are categorized by physiological processes controlled as well as by sequence.

Developmental, metabolic, neuromuscular, behavioral, and other physiological activities have been examined. Developmental neuropeptides include the ecdysiotropins that control levels of steroid hormones necessary for molting and egg production. The allatotropins and allatostatins regulate titers of specific fatty acids, juvenile hormones, responsible for determining developmental age. Metabolic neuropeptides regulate lipid mobilization, energy production, diuresis, and heart rate. Some behavioral neuropeptides control highly orchestrated movements required for eclosion (adult emergence), while others regulate the production of exquisitely specific and potent pheromones, volatile chemicals released by females to attract males. Myotropic neuropeptides represent a varied group, including FaRPs, that control locomotion, flight, egg laying, and the other neuromuscular demands of highly complex organisms. The literature on these and the many other arthropod neuropeptides is voluminous, and numerous reviews are available. Here, two neuropeptide families are presented as examples of the status of neuropeptide research in insects.

Pheromones are semiochemicals released by a female to attract a mate. In lepidopterans, the subesophageal gland produces pheromones in response to a neuropeptide – pheromone biosynthesis-activating neuropeptide (PBAN). PBAN was initially isolated from the moth *Helicoverpa zea* and subsequently identified and prepared from a number of other species. PBANs have only been identified in moths and butterflies, although a homolog is predicted in *Drosophila*. PBANs are 33 to 34 amino acids long, with high sequence homologies (~70–90%), and have an amidated C-terminus with a FSPRLamide motif. The

C-terminal pentapeptide was found to be the shortest PBAN fragment to retain pheromonotropic activity (its active core), a discovery that stimulated research to produce novel insect control agents based upon neuropeptides. The approach consists of two fundamental strategies. First, since pheromonotropic activity is retained within a short peptide sequence, it is possible to synthesize analogs of the C-terminus, and prepare various iterations containing different amino acid substitutions. The peptides are screened for antagonistic activity, and these lead sequences are used to design more potent antagonists. Second, peptides are polar molecules that do not readily pass through the insect cuticle, and are also susceptible to proteolytic attack within the animal. To address these problems, cyclic versions of lead peptides are synthesized such that polarity is reduced and resistance to proteolysis is increased. Through this approach, antagonists have been identified and the cuticle successfully penetrated. Improvement in design and potency of the peptide mimics, needed before practical use can be realized, represent major challenges, but the recent molecular cloning of the PBAN receptor will undoubtedly be of significant help.

A surprising feature of the PBAN FSPRLamide C-terminus is that it is shared among other neuropeptides with different biological activities and in various insect species. Myotropic neuropeptides called *pyrokinins*, isolated from cockroaches and locusts, stimulate muscle contraction in the gut and oviduct. They were also found to affect cuticle pigmentation in moth larvae, pupariation in flies, and pheromone production in moths. Reciprocal experiments demonstrated that moth PBAN could stimulate muscle contractions in other insects. Subsequent experiments have established a pyrokinin/PBAN family in insects. Common to all the neuropeptides examined was the FxPRLamide motif. In PBAN, $x = \mathrm{S}$, and in pyrokinin, $x = \mathrm{T}$. Cloning of the PBAN gene revealed a precursor peptide containing sequences of five peptides each containing the FxPRL structure. One sequence was PBAN and the other four are diapause hormone-like peptides, with FGPRLamide at the C-terminus. Thus, the FxPRLamide motif is associated with developmental and myotropic, as well as behavioral, activities. Specificity of action probably comes from association of the entire molecule with the receptor (as opposed to the active core only) and the population of receptors present in target cells.

Sequencing of the *Drosophila melanogaster* genome greatly expands analysis of insect neuropeptides. As with *C. elegans*, screens have been initiated to discover neuropeptide genes and genes for neuropeptide receptors. To date, 44 genes for G-protein coupled receptors (GPCRs) have been detected including those predicted to bind neuropeptide Y homolog, gonadotropin-releasing hormone, allatostatins, and a number of other receptors with homologs in humans, cnidarians, and other insects. The 22 neuropeptide genes discovered include those for adipokinetic hormone, ecdysiotropin, PBAN, and FaRPs.

FaRPs in *Drosophila* are sorted into three classes on the basis of amino acid sequences: sulfakinins, myosuppressins, and FMRFamides. All have neuromuscular activities, but these vary depending upon the tissue. Single genes were cloned for each group, only one gene for each group was found in the genome screen, and these had been cloned. The single FMRFamide gene codes for a precursor containing a total of 11 peptides with 6

different sequences. This compares with the multiple genes and sequences found in the lower invertebrates (e.g. nematodes). In molluscs, FMRFamide is also coded by a single gene. *Drosophila* FMRFamide receptors (GPCRs) have been cloned and characterized. They express varying preferences for the different *Drosophila* FMRFamides, suggesting that additional FMRFamide receptors may also exist and offer a source of specificity.

2.5 Molluscs

Since its discovery in the clam *Macrocallista* nearly 40 years ago, FMRFamide and related FaRPs have been described in nearly every invertebrate examined, and have stimulated a great deal of invertebrate neurochemical research. Molluscs have single genes coding for FaRPs but exhibit a variety of FaRP production strategies. The snail *Lymnaea* has a single five-exon FaRP gene that is alternatively spliced, resulting in 12 FaRP sequences including FMRFamide: The bivalve *Mytilus* gene codes for 16 copies of FMRFamide and three other peptides with no alternative splicing. In molluscs with the most complex nervous systems (the cephalopods: e.g. *Loligo*, squid; *Sepia*, cuttlefish), the single gene codes for 14 FaRPs including FMRFamide, and in *Aplysia*, a marine snail that has become a widely used model in neurochemical research, the FaRP gene encodes 28 copies of FMRFamide. The presence of a single FaRP gene in molluscs, as in insects, is in sharp contrast with the multiple gene strategy in the lower invertebrates.

The biosynthetic machinery that results in neuropeptide variety includes multiple genes and multi-exon genes, alternative gene splicing, propeptide and enzyme sorting, and posttranslational processing. One of the most prominent model systems used to examine neuropeptideff biosynthesis has been provided by *Aplysia*. The *Aplysia* nervous system is more sophisticated than the lower invertebrates, but contains relatively few and large neurons compared with vertebrates. Electrophysiological studies of stereotyped behavior and anatomical identification of the involved neurons were accomplished and, early on, the roles of neurochemicals including neuropeptides were examined. A most critical behavior in the gastropod molluscs is egg laying, and all of the above experimental approaches came to be focused on egg laying in *Aplysia*.

A remarkable feature of *Aplysia* is that egg laying is controlled by two clusters of peptidergic neurons, so-called bag cell clusters, each containing hundreds of homogeneous neurons producing the protein precursor of egg-laying hormone (ELH). Few systems allow the study of large numbers of homogeneous neurons producing one common precursor, and *Aplysia* became a particularly useful model for the study of neuropeptide regulation. The ELH gene encodes a 271 amino acid precursor containing the sequences for ELH, bag cell proteins (BCP) and acidic peptide (AP). These sequences are cleaved from the precursor and differentially packaged and transported. ELH is 36, BCPs range from 5 to 19, and AP is 27 amino acids long. The specific function of AP is not known, but all of the peptides act to coordinate egg-laying behavior. The extensive posttranslational processing of ELH peptides has been thoroughly studied, and the processing enzymes, including proconvertases, carboxypeptidase E, and the alpha-amidating enzymes have been characterized and their genes cloned.

3 Discussion

Invertebrates represent an enormous component of animal life, not only in terms of sheer numbers and biomass but also in diversity and distribution. Their importance to ecological health, and challenges to animal and plant health, makes their study of practical as well as academic importance. The examination of invertebrates is also essential in an evolutionary sense, as for example, in research on biochemical evolution. Throughout the invertebrate phyla, neuropeptides control all of the most critical physiological processes. The simplest nervous systems are biochemically complex, relying upon numerous neuropeptides to coordinate fundamental functions such as muscle contraction.

More complex animals use increased varieties of different neuropeptides in a number of families to control fundamental and specialized activities. While some neuropeptides such as PBAN are found only in a limited number of species, others such as the FaRPs are universally distributed among all of the phyla. Although processing mechanisms vary in specifics between the lowest and highest phyla, they are otherwise remarkably conserved and used by all invertebrates to produce active neuropeptides of all sizes. The enormous diversity among invertebrates is bridged by neuropeptides and their production.

Finally, studies of neuropeptide biochemistry and molecular biology in invertebrates have an effect on studies of all other animals. From the discovery of the neuroendocrine phenomenon in insects, genetic and developmental models in nematodes and *Drosophila*, and the neuropeptide processing contributions of *Aplysia*, invertebrate neuropeptide research continues to have far-reaching effects.

Keywords

Copy Number Polymorphism
A hallmark of noncoding, tandemly repeated DNA sequences referring to the observation that the copy number of an array is characteristically variable within a population or species.

Mechanisms of Copy Number Variation
DNA turnover mechanisms such as gene amplification, deletion, and unequal crossing over, and evolutionary processes such as genetic drift and natural selection on array size.

Noncoding, Tandemly Repeated DNA
Localized arrays of nucleotide repeats found in eukaryote genomes and usually classified as microsatellites (small tandem arrays of very short repeat units), minisatellites (larger arrays of longer repeat units), and satellite DNA (very large arrays of typically long, complex repeat units).

Selfish DNA
DNA sequences such as tandemly repeated sequences that may be responsible for significant fitness losses in the organism but are maintained by their ability to replicate quickly within the genome.

Noncoding, tandemly repeated dna sequences form a substantial fraction of the genomes of eukaryotes. In bacteria, however, large tandem arrays are not present. Some of the variation in genome size between different eukaryotic species, which bears little relation to differences in organismal complexity or the numbers of protein-coding genes (the *c-value paradox*), appears to be due to these nongenic sequences. This class of DNA includes satellite DNA (very highly repetitive sequences), minisatellite DNA (moderately repetitive sequences), and microsatellite DNA (short tandem arrays). In many cases, tandem arrays of noncoding DNA sequences seem to be maintained solely by their ability to replicate quickly within the genome (the *selfish DNA* hypothesis). Their behavior can result in mutations that cause human genetic disorders (e.g. fragile X syndrome). Features of the organization of tandemly repeated DNA sequences in eukaryotic genomes reflect the genetic mechanisms and evolutionary pressures acting on selfish DNA. New data from the human genome project provide a first glimpse on centromeric satellite DNA, a hitherto unexplored bastion of our genomes, and allow us to test previously proposed models of the evolution of highly repetitive sequences.

1 The C-value Paradox

The amount of DNA in an unreplicated haploid genome, such as that of the sperm nucleus, is called the *genome size* or, alternatively, *C-value*, because it is usually constant in any one species. In contrast to this relative constancy of genome size within species, great variation in C-value has been found among eukaryotic species. C-values in eukaryotes range from 2.9×10^6 base pairs (bp) to 6.9×10^{11} bp. The most dramatic differences are observed among unicellular organisms. For example, between *Saccharomyces cerevisiae* (yeast) and *Amoeba dubia*, variation in genome size is roughly 80 000-fold. Within a given taxonomic group, unicellular protists show the greatest range in genome size (20 000-fold). In contrast, the three amniote classes (mammals, birds, and reptiles) vary much less (1.3- to 4-fold). Most extensively studied eukaryote groups, whether plant, animal, or microorganism, show much greater variation in C-value than the amniotes. Protozoa exhibit a 1000-fold and unicellular algae, a 3000-fold range, whereas most classes of multicellular animals and plants show variation of the order of 10- to 100-fold. Great variation in C-value is, therefore, the general rule in most eukaryote groups; the relative uniformity found in mammals, birds, and reptiles appears to be an exception.

Given the relative constancy of genome size within species, it is puzzling that eukaryotes exhibit huge interspecific differences in C-value that bear little relation to differences in organismal complexity, ploidy level, or the percentage of coding DNA. For example, several unicellular protozoans possess more DNA than mammals; and the newt *Triturus cristatus* has around six times as much DNA as humans. This lack of correspondence between genome size and genetic information content has become known in the literature as the *C-value paradox*. The C-value paradox is particularly apparent in comparisons of closely related species, which, by definition, show similar levels of organismal complexity. Among protists, bony fishes, amphibia, and flowering plants, many sibling species differ greatly in their C-values. For example, the ciliate *Paramecium caudatum* has about 45 times as much DNA as *P. aurelia*.

Since a species does not contain less DNA than the amount required for specifying its vital functions in inheritance, the observed variations in genome size must be due to DNA that is in excess to this requirement. Eukaryotes with well-characterized genomes show a 30-fold variation in the number of protein-coding genes, ranging from 2000 in the parasitic microsporidian *Encephalitozoan cuniculi* to approximately 60 000 in *Oryza sativa*. Although this value is probably too low, the variation in the number of protein-coding genes observed so far is much too small to account for the 80 000-fold differences in nuclear genome size. Likewise, the C-value paradox cannot be explained by the interspecific variation in gene length because the several-fold variation in the average size of protein-coding genes (largely caused by variation in intron length) is also far too small to account for the C-value differences between species. On the other hand, the (repetition) number of RNA-specifying genes (e.g. ribosomal RNA genes) and the haploid DNA content are positively correlated; and a positive correlation also exists between the number of regulatory sequences (e.g. for replication) and C-value. Since, however, RNA-specifying genes and regulatory elements constitute

only a minute fraction of the eukaryotic genome, they cannot explain the great variation in genome size. On the basis of these observations, it has been concluded that the interspecific differences in C-values are largely due to nongenic DNA. It has been estimated that the amount of nongenic DNA per haploid genome varies in eukaryotes from less than 1.0×10^6 bp to more than 1.0×10^{11} bp. Nongenic DNA per genome makes up anything from less than 30% to almost 100% of the genome.

Classical studies of the kinetics of DNA reassociation showed that the eukaryote genome can be divided roughly into four fractions: foldback DNA (i.e. palindromic DNA sequences), highly repetitive DNA, middle-repetitive DNA, and single-copy DNA. The proportion of the genome consisting of repetitive sequences varies widely between taxa. In yeast, the amount of repetitive DNA is small (20%); in mammals, up to 60% of the DNA is repetitive. In plants, the amount of repetitive DNA can exceed 80%, and higher values than that have been registered. A large fraction of the repetitive DNA is noncoding and organized in tandem arrays. Thus, at least some of the variation in C-value is due to these noncoding, tandemly repeated DNA sequences (transposable elements are another major factor). The C-value differences between species are therefore caused by a *combination* of genetic and evolutionary forces acting on these repetitive sequences. Other authors have suggested that a single major mechanism (in particular, deletion bias leading to DNA loss) can account for the species-specific differences in genome size. However, although the data are scarce at present, it is unlikely that any such a mechanism alone can explain the C-value paradox.

2
Properties of Tandem Arrays

Variation in the numbers and lengths of tandemly repeated units occurs on many different scales. According to these characteristics, three major classes of tandemly repeated, noncoding DNA sequences can be distinguished: micro-, mini-, and satellite DNAs.

2.1
Microsatellite Sequences

Arrays of short (2–6 bp) nucleotide repeats, found in every organism analyzed so far, are called *microsatellite loci*; at least 30 000 are present in the human genome, located in the euchromatin. Copy numbers are characteristically variable within a population, typically with mean array sizes on the order of 100 but with multiple array size classes distributed around the mean. The distribution of microsatellites across the genomes of extensively studied organisms (e.g. man, mouse, and rat) appears to be relatively uniform. However, a significant deficit of $(CA)_n$ arrays (i.e. arrays in which the dinucleotide is repeated n times) has been found on the X chromosomes of these species. Contrasting evidence has been reported from several *Drosophila* species. More $(CA)_n$ loci (irrespective of their degree of polymorphism) have been detected on the X chromosome of *D. melanogaster* than on the autosomes. All autosomes show approximately equal numbers except chromosome 4, which has no detectable stretches of $(CA)_n$. Another striking feature is the lack of such repeats in the heterochromatic regions around the centromere. The same overall chromosomal pattern was seen by *in situ* hybridization in other *Drosophila* species, including *D. simulans*, *D. hydei*,

and *D. virilis*. The abundance of different repeat types varies between species. For example, the dinucleotide repeats $(CA)_n$ are very frequent in mammals, but rare in plants; and the trinucleotide repeat array $(CTG)_n$ is overrepresented in *Drosophila*, but is less frequent in other species. In general, all types of microsatellite sequences (from di- to hexanucleotide repeats) are found in frequencies higher than predicted on the grounds of base composition in noncoding genomic regions across seven eukaryotic clades: *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, *Schizosaccharomyces pombe*, *Mus*, *Drosophila*, plants and primates.

The discovery of the causative role of the expansion of microsatellites in several important human diseases (e.g. the fragile X syndrome of mental retardation) has revealed an unexpected practical significance to the studies of tandemly repeated noncoding DNA. The mutations causing neurological diseases such as the fragile X syndrome and myotonic dystrophy are preceded by *premutations* that lead to arrays of large size within the normal range of variation in the general population. The normal mechanisms operating on microsatellites (such as replication slippage; see Section 3) may play a role in the generation of premutation alleles by increasing array sizes by a few repeats at a time. At the onset of the full disease stage (when the length of the permutation alleles exceeds a certain threshold value), however, sudden large copy number changes occur.

2.2 Minisatellite Sequences

Minisatellite sequences are tandem arrays of longer (>15 bp) repeats, generally involving mean array lengths of 0.5 to 30 kilobase pairs (kb). They are found in euchromatic regions of the genome of vertebrates, fungi, and plants, and many minisatellites are also highly variable in array sizes. In contrast to hypervariable microsatellites, which are relatively uniformly dispersed throughout mammalian genomes (with the exception of X chromosome–autosome differences), the distribution of minisatellite loci across the genomes of some extensively studied species appears to be uneven. Hypervariable minisatellites are usually located in chromosomal regions of high recombination rates. In humans, most hypervariable loci have been localized to subtelomeric regions that have been found recombination proficient (particularly on metacentric chromosomes). In mice, the distribution of variable minisatellite loci seems to be more uniform, but the hypervariable minisatellites tend to be also located in recombination prone regions.

2.3 Satellite Sequences

Repeat units for satellites can be similar in length (2–30 bp) to micro- and minisatellites, or much larger (>100 bp). They are typically organized as large (up to 10^8 bp) clusters in the heterochromatic regions of chromosomes, near centromeres and telomeres, or on the Y chromosome. In plants, blocks of satellite sequences are also found interstitially (i.e. within euchromatic regions). Pulsed-field gel electrophoresis has shown that satellites are apparently not as variable in array size within populations as micro- and minisatellites (on a per-nucleotide basis). However, substantial differences in array size have frequently been observed between isolated populations and closely related species of both plants and animals. Satellite DNA families that are overabundant

in one species may be absent or in very low amounts in a sibling species. Species-specific satellite DNA clusters have been found in many organisms.

Another characteristic difference between satellite and minisatellite DNAs is the greater tendency for multimeric repeats to be found in satellites. The formation of higher-order repeats is particularly often seen in larger arrays (>200 kb). The best-studied example is the alpha satellite DNA family in primates. This consists of a basic repeat unit of 171 bp that is combined into various higher-order structures, ranging from dimers to (at least) 16-mers. The very highly repetitive satellite sequences can account for a large proportion of the DNA in the genome. Copy numbers of satellite DNA clusters range between 10^3 and 10^9. Arrays with shorter repeat units tend to have higher copy numbers. On average, the proportion of satellite DNA in the eukaryote genome is around 10%. Satellite DNA is virtually absent in yeast. But other species (including mammals) can possess more than 50% satellite DNA. For example, in the kangaroo rat *Dipodomys ordii*, 50 to 60% of the genome consists of three repeated sequences: AAG (repeated 2.4×10^9 times), TTAGGG (2.2×10^9 times), and ACACAGCGGG (1.2×10^9 times). The repeats within a tandem array are not completely identical. Interrepeat variability typically amounts to 5 to 10%. Another distinctive feature is related to their propensity to form higher-order structures: satellite repeats are often composed of subunits of simple sequences such as homopolymeric runs or short runs of di- or trinucleotide repeats. For example, the third satellite of the kangaroo rat contains both a homopolymeric run and a short stretch of dinucleotide repeats. Because of this simple nucleotide composition, satellite DNAs usually form one or more (*satellite*) bands in buoyant density gradients of genomic DNA, which are clearly distinguishable from the main band. This property led to the discovery of satellite DNA and to the name of this class of DNA. Satellite DNAs that cannot be separated from the main band by density gradients are known as *cryptic*.

The inability of current technology to determine a contiguous sequence for highly repetitive tandem arrays means that we know little about the sequence composition (such as the order of subfamilies) of satellite DNA clusters. However, high-resolution mapping of a human X-centromere border and sequencing of selected fragments recently provided a first glimpse into a large contiguous region of very highly repetitive DNA sequences of about 450 kb. This region between expressed sequences on the short arm of the X and the chromosome-specific alpha satellite array DXZ1 is satellite-rich. Repeat units of the DXZ1 array that forms the centromeric core are nearly homogeneous (98–99%), but homogeneity drops to around 70% toward the junction to the satellite-rich region (over a stretch of about 20 kb).

Micro-, mini-, and satellite DNAs comprise only a fraction of repeated, localized DNA sequences in eukaryotes. Interspersed DNA sequences, such as transposable elements, may also form clusters of repetitive DNA in certain parts of the genome after they have lost their ability to move. For instance, these nonfunctional transposable elements may be found as scrambled, clustered arrays in regions around the centromere at the boundary between heterochromatin and euchromatin. The individual sequence elements of these numerous arrays of moderately repeated sequences are usually <1000 bp in length. A cluster, which is several kilobase pairs

long, usually contains many different types of sequence, some of which may be repeated either directly or in inverted orientation. Different clusters within the same genome may share some, though not all, sequences, but the arrangement of shared sequences is not conserved between clusters. In this way, genetic and evolutionary mechanisms have created a considerable diversity of different types of repetitive DNA clusters that go beyond the three main tandem array classes discussed here.

3 Genetic Mechanisms of Copy Number Change

Several genetic mechanisms can affect the dynamics of tandem arrays: gene amplification by processes such as replication slippage and rolling circle amplification, unequal exchange, intrastrand exchange, and mutations by base substitutions (Figs. 1–3). However, the relative importance of these DNA turnover processes for micro-, mini-, and satellite DNAs, and the values of the parameters that describe them, are still uncertain.

In vitro studies suggest that strand slippage during DNA replication is the major cause of the observed length polymorphism of microsatellites between individuals within populations (Fig. 1). This process results in length changes of a few bases at a time. Dinucleotide repeats show a higher *in vitro* slippage rate than trinucleotide motifs; and those trinucleotides with the highest GC content have the lowest rates. In general, the *in vitro* data suggest that microsatellite arrays should be very highly variable in natural populations. The frequencies with which changes in array sizes occur at microsatellite loci are as high as a few percent per generation. These rates are much higher than normal mutation rates (due to base substitutions), but lower than expected from the *in vitro* results. Furthermore, there appears to be no relation between the occurrence of certain repeat types in eukaryotic genomes and their *in vitro* slippage properties. For example, $(GCC)_n$ repeats occur frequently in genomic DNA, but their *in vitro* slippage propensity is the poorest among all trinucleotides. These observations suggest that mechanisms other than slippage

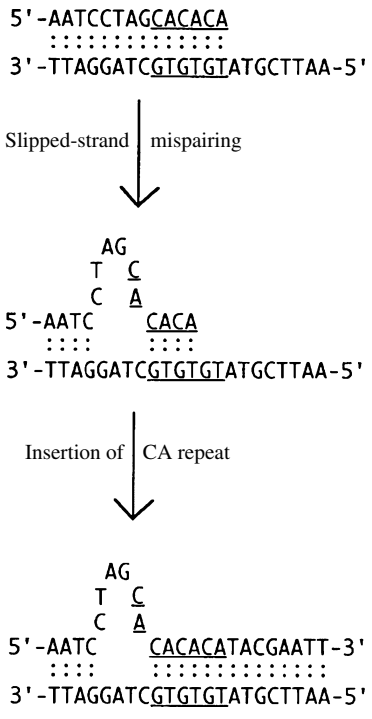

Fig. 1 Replication slippage: the newly synthesized strand (upper strand) is slipping in the 3′ → 5′ direction in the tandem array $(CA)_3$ (underlined). This leads to the insertion of an additional CA repeat as replication proceeds. Similarly, if the template strand (lower strand) slips in the 5′ → 3′ direction, a deletion of one or a few repeat units may occur.

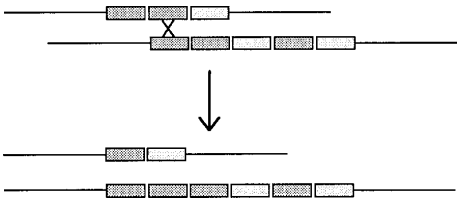

Fig. 2 Unequal exchange: unequal crossing over occurring between tandem arrays on homologous chromosomes. The boxes represent repeat units; heavy and light stippling indicates that the members of a tandem array may differ. Recombination is most likely to occur between repeats with the highest degree of similarity. Unequal exchange leads to the expansion of one array (lower one) and to the contraction of the other one. Furthermore, it results in more homogeneous arrays, a process called *concerted evolution*.

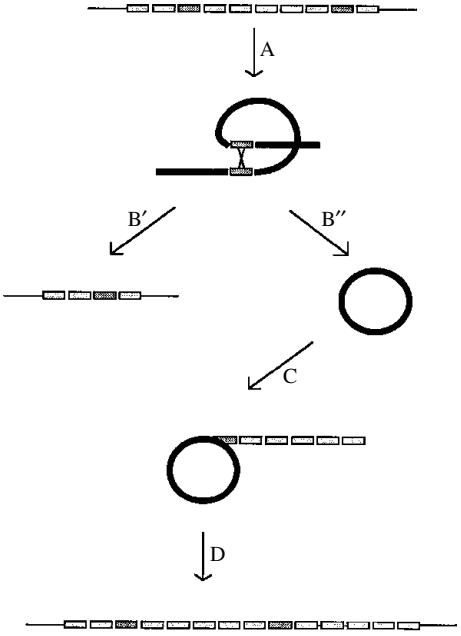

Fig. 3 Intrastrand deletion and rolling circle replication: pathway (A, B′), which includes the steps A and B′, results in a deletion of repeat units, whereas pathway (A, B″, C, D) leads to an amplification of repeats. In step A, pairing occurs between the two heavily stippled copies of the tandem array shown at the top (the other repeats are not shown). In step B′, this leads to the deletion of the repeats that are located between the two pairing repeat units (except one). In step B″, an extrachromosomal circular plasmid is created that carries the deleted repeats. Most of these plasmids are lost. However, some of them may undergo *rolling circle* replication. Step C results in the replication of all copies of this circle. In step D, these amplified repeats are reintegrated into the tandem array by recombination.

must contribute to the dynamics of simple repeats in organisms.

There is a relation between replication slippage of microsatellite sequences and defective DNA repair, since mutations in DNA repair genes can cause tract instability in yeast when errors resulting from slippage replication remain unrepaired. Similarly, a mutation in a gene of the same mismatch repair system in humans can lead to expansion of microsatellite tracts associated with human disorders such as colorectal cancers. These observations may suggest that replication slippage is the primary force involved in the expansion and contraction of microsatellite arrays, but that most of the length changes because of slippage are corrected by the DNA repair system. In addition, unequal exchanges could occur in microsatellite arrays that

are sufficiently large (Fig. 2). Total array size, however, appears to be an important constraint for the occurrence of unequal exchange. In contrast to replication slippage, unequal exchange is an interhelical event, involving DNA molecules from two different sister chromatids or homologs. This may place some constraints on the length of the sequences undergoing unequal exchange. Large changes in copy number, which are occasionally observed at microsatellite loci in population surveys (see Sect. 7), may result from unequal exchanges.

Several processes may cause the instability of arrays of minisatellites. At some well-studied human minisatellite loci, a bias toward gains of a few repeats has been found, with gains occurring preferentially at one end of a tandem array. New repeats on a given chromosome can originate either from the same chromosome or from its homologue. A gene conversion-like mechanism causing this net increase in copy number has been proposed. In addition, unequal exchange could occur between tandem arrays on sister chromatids or between arrays on homologous chromosomes. At present, however, there is no direct evidence for unequal exchanges at minisatellite loci. The frequencies with which changes in array sizes occur at minisatellite loci are similar to those of microsatellites and can be as high as a few percent per generation. At extremely variable loci, mutations to new length alleles occur at a rate high enough to measure it by direct observation in pedigree analysis. The apparent relative stability in populations of small minisatellite alleles provides indirect evidence that the expansion and/or contraction of minisatellite arrays may occur at a frequency dependent on array size, such that longer arrays exhibit a higher rate of copy number change.

The forces governing the dynamics of satellite DNA are more difficult to understand, mainly because the large sizes of satellite DNA clusters preclude direct experimental analysis, and also hinder the collection of meaningful population data. However, new advanced mapping techniques, in combination with genomic sequencing, have recently revealed some of the complexity of satellite DNA arrays and also advanced our knowledge about the mechanisms acting on these sequences. Since replication slippage involves only a short stretch of DNA at a time, it probably plays only a minor role in the amplification of the longer satellite repeat units (>100 bp). Slippage may, however, be important in the initial formation of satellite repeats that are generally composed of smaller subunits (see Sect. 2.3). The observation of extrachromosomal circular satellite DNA suggests the possibility that long satellite repeats may primarily be amplified by extrachromosomal rolling circle replication, followed by reinsertion into the genome (Fig. 3). The best evidence for the occurrence of unequal exchange comes from the analysis of the human DXZ1 alpha satellite. A large stretch of the DXZ1 satellite toward the middle of the array consists of homogeneous repeat units, but sequence similarity among repeats drops relatively quickly toward the edge of the array. Such a pattern can only be explained by unequal crossing over, not by any other mechanism of sequence homogenization such as gene conversion (see Sect. 6.3). The question of whether unequal exchange occurs predominantly between sister chromatids or between homologues is, however, still open. If recombination occurs either between arrays on sister strands or between different homologues, it is also likely

to occur between members within a strand. This process, called *intrastrand exchange* or *intrastrand deletion*, is expected to result in deletion of members on that array (Fig. 3). In fact, the finding of extrachromosomal DNA circles containing satellite repeats is the best available evidence that intrastrand exchange occurs in large tandem arrays. Most of the extrachromosomal plasmids carrying copies of the array may be lost. However, some of these plasmids may undergo rolling circle replication, which amplifies a small section of the array before integration into the array.

4 The Selfish DNA Hypothesis

It has often been proposed that tandem-repetitive DNA sequences are functionally important for the host organism. The *Responder* satellite sequences of the *D. melanogaster* segregation distorter system seem to affect the fitness of their carriers. The *Responder* locus in natural populations of *D. melanogaster* consists of 20 to 2500 copies of a 120-bp repeat unit. In a competition experiment involving a mixed population of flies with 700 copies and flies with 20 copies, it was observed that the frequency of the flies containing 20 copies decreases with time. This may suggest that flies with 700 copies have a higher fitness than flies with 20 copies. However, there is a potential problem with this experiment in that the chromosomes carrying 20 copies contain a large deletion that includes a segment of DNA flanking the *Responder* satellite.

There is also evidence for biological effects of heterochromatin (which is rich in satellite sequences), such as the formation of heterochromatic genomic compartments important for proper chromosomal segregation in mitosis and meiosis. Satellite DNAs appear to be major constituents of functional centromeres, as has been shown in *Drosophila* and humans. Similarly, there appears to be an effect of minisatellites on the expression of genes that are located nearby. For example, the 14-bp minisatellite in the diabetes susceptibility locus *IDDM2* contains high affinity–binding sites for the transcription factor, Pur-1 and may stimulate insulin transcription. It has therefore been suggested that this result demonstrates a possible function of the insulin minisatellite.

But these properties of minisatellite and centromeric satellite DNA may not have a role in the origin and maintenance of tandemly repeated sequences: they could simply be a response to their presence in the genome, that is, consequences rather than causes. That the insulin repeat is found in much lower copy numbers in other primates (e.g. chimpanzees) and is absent in nonprimates seems to support this hypothesis, although it does not completely rule out the possibility that this repetitive structure is the result of a recent adaptive process. The large differences in amounts of satellite DNA sequences between closely related species (see Sect. 2.3), and the absence of measurable fitness effects of large deletions or duplications of heterochromatin in *Drosophila*, also suggest strongly that selection does not actively maintain the high copy numbers of many of these sequences.

It has therefore been proposed that in most cases, tandemly repeated noncoding DNA sequences are maintained solely by their ability to replicate quickly within the genome (the *selfish DNA* hypothesis). Far from conferring benefits, their behavior can result in a fitness loss to the host. Some human genetic diseases are known to be caused in this way, including mutations

due to the amplification of microsatellite sequences (see Sect. 2.1).

5 Evolutionary Dynamics of Tandem Arrays

Because of an obvious lack of functional significance and technical constraints, many aspects of the biology of tandemly repeated, noncoding DNA sequences cannot be explored by direct experimentation. In this section, some basic theoretical concepts that have been used to understand the properties of this class of DNA are introduced. It is shown that many features of the organization of tandemly repeated DNA sequences in eukaryotic genomes may be explained on the basis of the selfish DNA hypothesis (Sect. 4) and the genetic mechanisms outlined in Sect. 3.

5.1 The General Model

The state of a haploid genome with respect to a given class of tandemly repeated DNA sequences at a particular chromosomal location is characterized by i, the number of repeats in the array. The state of the population is described by the distribution of values of i among haploid sets, such that x_i is the frequency of chromosomes with array size i. The following factors affect the change of this distribution over time. Experimental evidence for these mechanisms is discussed in Sect. 3.

Amplification: A sudden increase in array size by one or more repeat units. Depending on array type (see Sect. 3), it may involve replication slippage (Fig. 1), gene conversion-like processes, rolling circle replication of extrachromosomal repeat units followed by reinsertion (Fig. 3), or other, unknown, mechanisms (e.g. in disease-related microsatellites).

Deletion: A sudden decrease in array length by one or more units, caused by replication slippage or intrastrand exchange (Fig. 3).

These two processes can be included in a model in which the probability that an array of length j generates an array of length i is $\alpha_j P_{ij}$, where α_j is the probability that a change of an array of length j occurs per generation, and P_{ij} is the conditional probability of the change from j to i. Although there is evidence that array size affects the rate of copy number change, assume here for simplicity that all α_j are identical.

Unequal exchange: This can occur either between homologous chromosomes or between sister chromatids. Only the first category is considered here (Fig. 2). Let γ_{jk} be the probability of an exchange between an array of j and an array of k copies, and Q_{ijk} be the conditional probability that an exchange produces a daughter chromosome with array size i from parental chromosomes with copy numbers j and k ($0 < i < j + k$). There is an equal chance of production of a daughter with $j + k - i$ copies. The probability of the production of a daughter chromosome with i (or $j + k - i$) copies is then $\gamma_{jk} Q_{ijk}$. Again, for simplicity, it is assumed that all γ_{jk} are identical ($= \gamma$).

Natural selection: According to the selfish DNA hypothesis, selection is usually assumed to be nonexistent or very weak (i.e. fitness declines very slightly) until array sizes reach a relatively high value. Above a certain threshold value Ω, however, fitness is assumed to drop rapidly to zero with increasing numbers of repeats for individuals carrying more than Ω copies. The

threshold effects observed in the dynamics of disease-related microsatellite loci (see Sect. 2.1) seem to suggest that such abrupt changes in fitness may occur. Base substitutions in the sequence are generally considered to be selectively neutral.

Genetic drift: As a result of finite effective population size N_e, the frequencies of haploid genomes with different array sizes are subject to multinomial sampling during reproduction in the same way as a conventional multiple-allele system with allele frequencies x_i.

Mutation: Mutational differences in sequence (occurring at rate μ) among members of an array may affect their probability of undergoing strand pairing during recombinational processes. Recombinational steps are believed to be important in several DNA turnover processes that operate on tandem arrays (e.g. unequal exchange, rolling circle replication, gene conversion-like amplification). Mutational differences among the repeat units also have a strong impact on the rate of strand slippage during replication because these differences, which appear as mismatches in strands that are reannealed out of register, can be more easily detected by the DNA repair system when they are more frequent.

5.2 Copy Number Dynamics of Tandem Arrays

The qualitative behavior of this model can best be studied by considering the persistence times of tandem arrays. In this approach, it is assumed that a certain distribution of array sizes exists at a given initial time in the population, generated by a sudden amplification event. In the absence of further amplifications, these tandem arrays are lost from the population owing to the joint action of DNA turnover processes, genetic drift, and selection. A discussion of unequal exchange as a typical DNA turnover process that can affect copy number is now given; but other processes with similar properties can be substituted or added, as will be shown. Natural selection is modeled such that fitness of an individual in the population decreases slowly with increasing copy number and declines rapidly to zero when copy number is larger than a threshold value Ω. This selection scheme is consistent with the selfish DNA hypothesis. Unequal exchange can both expand and contract a tandem array with equal probability and by equal amounts; hence, on average, mean copy number does not change from generation to generation. However, unequal exchange, in conjunction with genetic drift and selection, leads to a decrease in mean copy number over time until the population has reached a state in which it is fixed for chromosomes with array size 1, and unequal exchanges are no longer possible. The average time to loss of a tandem array is inversely proportional to γ the frequency of unequal exchanges per generation, if γ is sufficiently small ($4N_e\gamma < 1$); furthermore, it increases with Ω, and decreases with increasing effective population size N_e. However, if $4N_e\gamma$ exceeds 1, the expected time to loss of a tandem array from the population increases with increasing population size. This behavior of the model is summarized in Fig. 4.

Four predictions that can be compared with the data (see Sect. 6) follow immediately from these results:

1. Longer tandem arrays persist in regions of low rates of unequal exchanges.
2. More variable arrays are less conserved over evolutionary time.

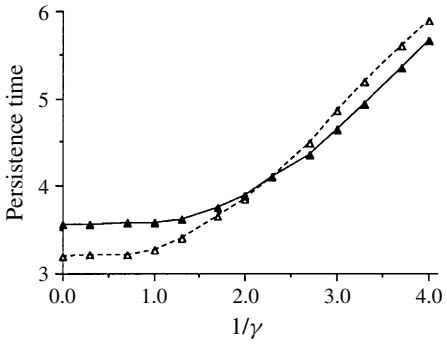

Fig. 4 Persistence time of tandem arrays versus inverse recombination rate. The mean time to loss of tandemly repeated DNA sequences (in generations) under the joint action of unequal exchange, genetic drift, and selection on array size is plotted against the inverse recombination rate in a double-logarithmic fashion. It is assumed that amplification processes are not operating and that the mean copy number of the population is initially 50. The results have been generated by computer simulations for two population sizes, $N_e = 50$ (open triangles) and $N_e = 200$ (solid triangles), and a maximum array size of $\Omega = 10\,000$. Note the dramatic increase in persistence time as the recombination rate decreases. Furthermore, note that the effect of N_e on persistence time is reversed for small and large values of γ. Because of the logarithmic scale of the y axis, the persistence times between the two populations differ for both small and large values of roughly by a factor 2. That means effective population size, in addition to recombination rate, can have a dramatic effect on the persistence of tandem arrays in populations. In contrast, the effects of initial copy number and selection (Ω) are less pronounced.

3. Tandem arrays are larger and persist longer when selective constraints on array size are weak (i.e. larger Ω).
4. Tandem arrays are larger and persist longer in populations whose effective size N_e is small.

Predictions 1 and 4 may not be intuitively obvious and need additional explanation. In regions of low rates of crossing over, arrays with high copy numbers are not frequently generated by unequal exchange; thus, selection is less effective in eliminating from the population individuals whose copy numbers are too high. As a result, mean array size decreases slowly, which explains prediction 1. Indeed, a detailed analysis of the model indicates that the effect of unequal exchange on the persistence of arrays is particularly pronounced in regions of very low rates of crossing over, suggesting that array sizes of tandemly repeated sequences should be much larger in regions of reduced rates of exchange than in those of intermediate or high rates of crossing over. Prediction 4 is a consequence of the interaction of genetic drift and selection on array length. In populations with small effective sizes, random fluctuations of the frequencies of alleles containing tandem arrays due to genetic drift are more dramatic than in populations with large effective sizes. Therefore, in small populations, drift is stronger and can overcome the effects of selection pressure on array size. This reduces the efficiency with which alleles whose copy numbers are too high are removed from the population by selection, and increases the persistence times of tandem arrays.

The foregoing results are not limited to unequal exchange, which is thought to act primarily on larger tandem arrays such as minisatellites and satellite DNAs. Any other mechanism that is symmetrical with respect to copy number change can be

substituted for unequal exchange such that the results are essentially unchanged. For example, replication slippage (operating on microsatellites) and unequal exchange would have qualitatively similar effects on copy number dynamics.

When recurrent amplification processes are included in the model, an equilibrium array size will result as a balance between amplification (leading to a net increase in copy number) and unequal exchange, genetic drift, and selection (causing a decrease). A particularly interesting prediction of this model that may pertain to satellite DNA is the following: as a result of amplification in combination with selection against high copy numbers, unequal exchange, and genetic drift, mean array size is high only when $4N_e\gamma$ is less than 1 and is highest when selection against arrays is weakest, as might be the case for organisms with long developmental times. Thus, satellite sequences should accumulate in chromosomal regions of very low rates of unequal exchanges, and more slowly developing species should possess more repetitive DNA.

5.3 Sequence Homogenization

Computer simulations of the general model for tandem arrays have explored the relation between copy number change and sequence variability between members of a tandem array. In these models, mutation was allowed to alter the sequence of repeat copies by base substitution. This has consequences for the probability that copies can recombine in unequal exchanges, and strands reanneal during replication slippage. In other words, the exchange rate and amplification rate were assumed to be dependent on sequence similarity. As suggested by experimental evidence from several different *in vivo* and *in vitro* systems, it was assumed that a short stretch of perfect sequence identity rather than long segments of overall homology is required for a successful turnover process to occur. The outcomes of these simulations are remarkable:

1. Tandem arrays of repetitive sequences can be generated *de novo*, starting from a random DNA sequence.
2. Short simple repeat sequences emerged when the sequence-dependent DNA turnover processes occurred frequently; in contrast, arrays with longer repeat units (including higher-order structures such as multimeric repeats) were generated when the rates of amplification and exchange were low. A related phenomenon is that the basic repeat units often exhibited an internal substructure featuring runs of homopolymeric nucleotides and/or short stretches of di- or trinucleotide repeats.
3. A positive correlation between the rate of unequal exchange γ and sequence homogeneity between repeat units within a tandem array was observed. Remarkably, however, sequence homogeneity remained relatively high and did not drop below a certain threshold level until γ was reduced dramatically relative to the mutation rate μ.
4. Weak selective constraints (i.e. large Ω values) led on average to larger repeat units and increased the tendency to form higher-order structures.

6 Comparison of Theory and Data

This section compares the theoretical results from Sect. 5 with the properties of tandem arrays.

6.1 Microsatellites

Microsatellites have very short and homogeneous repeats and a very small total array size. They are distributed in euchromatic regions of the genome in a relatively uniform manner and have been found near and within gene regions. The theoretical and experimental analyses suggest that these properties are consistent with high rates of DNA turnover mechanisms (in particular, replication slippage) and strong selective constraints on total array size (small values of Ω). As a consequence of these high turnover rates, most microsatellite arrays are highly variable within populations. Furthermore, as expected, there appears to be an inverse correlation between the degree of intraspecific variability of copy number and interspecific conservation of microsatellite loci, such that the more variable loci exist only over a narrower phylogenetic range. However, some simple repeat loci do not follow the predictions of the proposed model in that they show fewer interspecific differences in copy number than expected on the basis of the degree of intraspecific variation. In these cases, functional explanations may have to be invoked to describe their evolutionary dynamics.

Conflicting evidence has been reported from a number of well-studied species with respect to the abundance of microsatellite loci on X chromosomes versus autosomes (see Sect. 2.1). There is a significant lack of highly polymorphic $(CA)_n$ loci on the X chromosomes in several species such as man, mouse, and rat; on the other hand, in *Drosophila*, the total number of $(CA)_n$ microsatellites (poly- and monomorphic ones) on the X chromosome is slightly higher. This uneven distribution in *Drosophila* is consistent with the theoretical model discussed earlier. Since the rate of copy number change for *Drosophila* microsatellites is generally very low and the effective population size of the X chromosome in *Drosophila* is smaller than that of the autosomes, one should expect that the forces for removal of repetitive DNA are weaker on the X chromosome and that therefore more loci persist. A smaller effective population size increases the effect of genetic drift relative to selection and thus alleviates the constraints imposed by selection on total array size. As a consequence, the removal of repetitive DNA is less efficient. Thus, it is not necessary to invoke hypotheses about differences in the genetic mechanisms between the X chromosome and the autosomes or functional explanations to understand the uneven distribution of the number of microsatellite loci. In contrast, the deficit of highly polymorphic microsatellites on the X chromosome in the three mammalian species is probably not compatible with this model. For a population undergoing replication slippage (by single steps) and genetic drift, it has been shown that the persistence time of microsatellites does not depend on effective population size in a linear fashion. Thus, the 30% deficit of hypervariable microsatellites is better explained by a lower rate of replication slippage, owing to the fact that the X chromosome is present less often than the autosomes in the male germ line, which is thought to be more mutation prone in mammals.

6.2 Minisatellites

The salient properties of minisatellites may also be explained by the proposed model. Minisatellite loci are found in the euchromatin. Many of them are

highly polymorphic, though not, on a per-nucleotide basis, as polymorphic as microsatellites. Their repeat units are longer, and their total array sizes are much larger than those of microsatellites. These properties are consistent with the predictions of the model if smaller rates of DNA turnover are assumed. Indeed, the per-base-pair turnover rates that have been estimated by direct observation in pedigree analysis are substantially lower than those of microsatellites. The relatively large array sizes of minisatellites indicate that selective constraints on total array size are weaker than for microsatellites, possibly because minisatellites do not appear to be located as close to gene regions as microsatellites.

It is unknown at present why highly polymorphic minisatellite loci tend to cluster in subtelomeric regions of the human genome. However, since the genetic map is extended in these portions of chromosomes, recombinational steps may generally occur at a higher rate in these regions. Recombinational steps are involved in processes such as gene conversion-like amplification, unequal exchange, and intrastrand exchange, which are thought to operate on minisatellites (see Sect. 2.). According to the proposed model, increased rates of DNA turnover should lead to a high degree of copy number variation and may therefore explain the overabundance of hypervariable minisatellites in these regions.

Because of a lack of exchange of flanking markers, unequal exchange between homologues is probably not the predominant mechanism of copy number change at minisatellite loci. However, there is indirect evidence for the occurrence of unequal exchange between sister chromatids. In accordance with the predictions of the model, it has been found for a sample of human minisatellites with different degrees of allelic variability in repeat copy number that a significantly negative correlation exists between copy number variability and interrepeat sequence variability (see Fig. 5). In other words, the most highly polymorphic loci (with respect to copy number variation) show the highest degree of sequence homogeneity between repeat units. This homogeneity in tandem arrays is difficult to explain by events that are restricted to certain parts of arrays, such as the gene conversion-like amplification mechanism mentioned in Sect. 3. Instead, long-range forces such as unequal exchange that act over a large distance of an array must be invoked. Furthermore, as expected from the theoretical analysis, minisatellites that are highly polymorphic within species are evolutionarily unstable. For example,

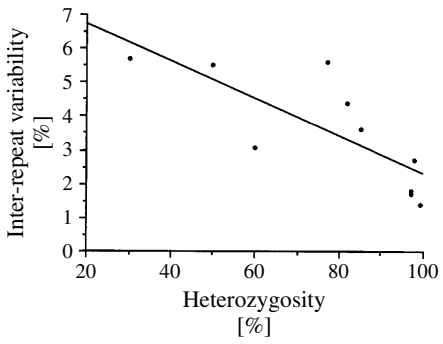

Fig. 5 Interrepeat variability versus allelic heterozygosity for human minisatellite loci: allelic heterozygosity caused by copy number variation versus sequence variation between members of a tandem array. The negative correlation between allelic heterozygosity and sequence heterogeneity is highly significant ($P < 0.01$). [Reproduced from Stephan, W., Cho, S. (1994) Possible role of natural selection in the formation of tandem-repetitive noncoding DNA, *Genetics* **136**, 333 – 341, with permission.]

comparisons between humans, great apes, and monkeys have shown that minisatellite arrays that are highly polymorphic in humans (e.g. minisatellite locus *MS32*) are sometimes very short and relatively monomorphic in great apes and monkeys (3–4 repeats for *MS32*).

6.3 Satellites

The interpretation of the properties of satellite DNA is the greatest challenge for the proposed model because this data set is relatively complex, and despite a long history of research and some new results (see Sect. 2.3), not as comprehensive as those of micro- and minisatellites. Satellite DNA can form short repeat units that are similar in length to micro- and minisatellite repeats and also very large ones (>100 bp). In any case, their total array sizes are much larger than those of micro- and minisatellites. In contrast to the two latter classes of DNAs, satellites are located in heterochromatic regions of chromosomes. These properties of satellite DNA are clearly compatible with weak selective constraints on array size, probably because satellites are located in heterochromatin that is devoid of functional genes (for reasons given shortly). Furthermore, the features of satellite DNAs are compatible with low rates of DNA turnover mechanisms such as unequal exchange and rolling circle amplification that produce copy number variation and sequence homogeneity in these tandem arrays. The short repeat length of some satellites may raise a caveat to this interpretation, but computer simulations of the general model have demonstrated that repeat unit lengths of the simulated arrays may vary greatly when the rate of DNA turnover is low relative to the nucleotide substitution rate μ. This interpretation is also consistent with the absence of microsatellites from heterochromatin (see Sect. 2.1). Tandem arrays of very short repeat units that are located in heterochromatin, often juxtaposed to satellites with longer repeat units (e.g. in humans and *Drosophila*), are much longer than microsatellites (Sect. 2.3).

Direct evidence for low rates of DNA turnover processes in heterochromatic regions near centromeres and telomeres has been found for meiotic recombination. Contraction of the genetic map suggests that meiotic recombination is strongly suppressed in regions near the centromeric and/or telomeric heterochromatin in several well-studied species, including human, *Drosophila*, and yeast. The causes for this reduction are unknown, although it may be selectively advantageous for recombination to be suppressed near centromeres. Since recombinational steps are involved in essentially all DNA turnover mechanisms that alter copy number of satellite arrays, it is possible that there is a general reduction of the rates at which these processes occur in heterochromatin. As a consequence, unequal exchange between homologues as well as between sister chromatids, intrastrand exchange, and rolling circle amplification may be less frequent than in euchromatin. It therefore seems likely that suppression of recombination (or, in general, of recombinational processes) is the primary cause for the accumulation of satellite sequences.

This hypothesis is consistent with the observation that satellite sequences show a greater tendency to higher-order structure (multimeric repeats) than minisatellites (Sect. 2.3). Computer simulations of the general model suggest that higher-order structures are preferentially found in regions of low rates of unequal exchange

and weak selective constraints on total array size. Additional evidence that rates of DNA turnover in satellites are low comes from the observation that satellites, in sharp contrast to micro- and minisatellites, show little variation in copy number within populations, relative to their large array sizes (Sect. 2.3). However, substantial differences in array size are often observed between closely related species of animals and plants, indicating that processes causing expansion or contraction of satellite arrays must occur at a significant rate on an evolutionary timescale. Evidence that a minimal level of DNA turnover occurs in satellite DNAs also comes from the observation of a high degree of sequence homogeneity in the middle of satellite arrays and much lower homogeneity at the edge. The simulations indicate that unequal exchange is a strong long-range homogenization force that may operate over the entire array length. However, rates of exchange cannot be too low relative to the rate of point mutations; otherwise, it would not be possible to maintain the observed degree of sequence homogeneity in satellites, which is as high as 98 to 99% in the core of the DXZ1 satellite of humans (see Sect. 2.3).

In sum, the great majority of tandem arrays of noncoding DNA studied so far follows the predictions of the proposed model that was based on the selfish DNA hypothesis and included a suite of DNA turnover processes. A purely neutral model in which fitness of an individual is not affected by the amount of tandemly repeated DNA would have accounted for most of the properties of micro, mini, and satellite DNA. However, some of the observations, such as the distinctly different chromosomal locations of these classes of DNA in euchromatin versus heterochromatin and the effects of population size on the higher abundance of microsatellites on X chromosomes versus autosomes in *Drosophila*, cannot readily be explained without invoking the idea of selection acting against high copy number. Thus, it appears that tandem arrays are subject to generally weak selective constraints on array size, as predicted by the selfish DNA hypothesis.

7 Population Processes

Noncoding, tandemly repeated DNA provides population biologists with the great opportunity to study processes such as migration and population differentiation, population structure, and genetic relatedness at the molecular level. Most prominent is the use of minisatellite loci as evidence in legal proceedings, usually in the determination of paternity or individual identification in forensic medicine. Population genetic models of tandem arrays generally assume that they are nonfunctional, that is, neutral or slightly deleterious. Base substitutions in the sequence are considered to be selectively neutral, but there may be natural selection against increased array size. In other words, these models are similar to those described in Sect. 5. Alternatively, it is assumed that point mutations prevent microsatellite arrays from growing too long. This assumption is based on the notion that the slippage rate depends on the homogeneity of the repeats.

The frequency distributions of length alleles at microsatellite loci in most populations fit a *stepwise mutation* model quite well. In such a model, arrays increase or decrease in repeat number

by one or a few repeats, with occasional increases by larger steps. The fit of the population data to this model suggests that mutational steps usually involve only very few repeat units, as with slippage replication. This confirms the results of the *in vitro* studies of microsatellites reported in Sect. 3.

In contrast to microsatellites, the length distributions of minisatellite alleles do not fit a stepwise mutation model. This suggests that events that alter copy number occasionally involve many repeat units, as can happen with unequal exchange. On the other hand, the population data are not consistent with a model in which every new array that appears in the population is unique, as would be expected if events such as unequal exchanges with unconstrained misalignment were frequent. For satellite DNAs, only a very limited amount of population data is available at present; therefore, no efforts have been made thus far to analyze the length distributions of satellite alleles within populations.

Primary Literature 242

Keywords

Adult Stem Cells
Undifferentiated multipotent (able to give rise to a subset of cell lineages) cells capable, at the single cell level, of proliferation, self-renewal, and the production of differentiating daughter cells.

Animal Cloning
Production of genetically identical progeny from a founder; different techniques can be used (e.g. embryo disaggregation, embryo splitting, or nuclear transfer).

Cloning Efficiency
Proportion of all cloned embryos transferred into surrogate mothers that develop into viable offspring.

Cytoplast
An oocyte, zygote, or 2-cell blastomere whose nuclear DNA was removed or destroyed.

Embryonic Stem (ES) Cells
Immortal pluripotent (able to give rise to all cell types of the embryo proper) cells derived from placing inner cell mass blastomeres into *in vitro* culture.

Epigenetic
Changes in gene activity that do not entail changes in DNA sequence. These changes are stably maintained through DNA replication and include covalent modifications of DNA and DNA-binding proteins.

Mitochondrial Heteroplasmy
Presence of more than just the maternally inherited types of mitochondria within a cell.

Nuclear Reprogramming
The process of returning a differentiated nucleus to a totipotent stage.

Nuclear Transfer (NT)
Procedure in which the complete chromatin content from one cell (e.g. somatic donor) is moved to another (e.g. recipient oocyte), either by microinjection or membrane fusion.

Reproductive Cloning
Cloning of progeny from diploid cells; in humans, banned in most countries.

Serial Nuclear Transfer
Procedure in which the product of the first NT step is allowed to cleave and form pronuclei which are then each transferred into another enucleated recipient cell (usually a zygote or a 2-cell blastomere). The second NT step capitalizes on the better developmental potential of correctly fertilized zygotic cytoplasm.

Tetraploid Embryo Complementation
An indirect two-step cloning procedure, whereby cloned blastocysts, derived from nuclear transfer, are used to generate ES cells for injection into tetraploid host blastocysts. The cloned ES cells form the entire embryo proper, whereas the complementing tetraploid host cells form the placenta.

Telomere
Structures that ''cap'' the ends of mammalian chromosomes and prevent repair mechanisms that would result in end-to-end chromosomal fusions. In the absence of the telomerase enzyme, they progressively shorten as a consequence of cell division.

Therapeutic Cloning
Deriving stem cells from embryos created with somatic cells of a human patient in order to produce immunologically compatible replacement cells for the same patient.

Xenotransplantation
Transplantation of tissues or organs between different species.

Nuclear transfer (NT), also called *nuclear replacement*, or *nuclear transplantation* is the method of choice for animal cloning. NT is a complex technique, which involves the removal/destruction of the nuclear DNA from an oocyte or zygote (enucleation), and replacing it with nuclear material from an embryonic or somatic cell. The newly introduced DNA interacts with the recipient cytoplasmic environment, and following complex and little known changes in the nuclear DNA, in some cases, will develop into adult fertile animals. Nuclear transfer is an important procedure as it allows addressing fundamental questions on epigenetic ''reprogramming.'' As a practical tool, it can be used for agricultural and medical applications, especially combined with transgenic and embryonic stem cell technologies.

1 Introduction and Brief Historical Overview

The word ''cloning'' comes from the Greek ''$\kappa\lambda o\nu$,'' meaning twig. Indeed, many plants and simple organisms can routinely reproduce asexually. In vertebrates, however, initial cloning experiments were not aimed to study reproduction, but to understand the differentiation process of the genetic material during development. The basic idea was not new, historic experiments in the 1930s by Spemann on salamanders paved the way for later studies to explore functional changes in the nuclear genome during differentiation. These pioneering experiments in Amphibia revealed many basic mechanisms, which are similar in mammals. Despite the fact that currently most of the attention is being paid to the mammalian systems, the progress could not have been achieved without the lessons that were learnt in frog experiments.

Starting in the 1950s, with two frog species, *Rana pipiens* and *Xenopus laevis*, it was shown that embryonic cell nuclei transplanted into enucleated eggs reacquire a totipotent status and can develop into normal adults. Experiments using differentiated cells taken from adults were less successful, and only supported development to the swimming tadpole stage. Nevertheless, these studies proved that the donor cells retained all genetic information to form heart, muscle, brain, and all the other cell types in a tadpole, demonstrating that the genome is entirely preserved throughout cell differentiation and growth. Studies in amphibians and then in mammals revealed that the potential of the nucleus to direct embryonic development decreases progressively with the developmental stage of the donor cell.

In mammals, the first experiments in the 1980s using embryo-derived blastomeres and sophisticated micromanipulation systems resulted in the birth of numerous animals. This created a new commercial interest in multiplying high-value farm animals through cloning. Owing to the results in amphibians, researchers were initially discouraged to use adult donor cells for cloning. This radically changed with the birth of a lamb (''Dolly,'' in 1996) cloned from an adult donor's mammary gland cell, showing that even such differentiated somatic cells maintain a remarkable flexibility, and this opened new possibilities to ''copy'' existing individuals. Success of producing embryos and progeny in various laboratory, farm and endangered

species followed, and, in 2004, good quality human embryos were obtained from adult somatic cells.

The possibility of ''xeroxing'' existing individuals captured the imagination of the media and the public. In the true sense of the meaning the new individuals are not ''genetically identical clones'' as cytoplasmic contributions in each may vary and some of the genetic processes, for example, random X chromosome inactivation patterns in female mammalian ''clones'' would differ (see details in Sect. 2.3.). Furthermore, the absence of any chromosomal rearrangements would have to be demonstrated. The procedures involve numerous, technically demanding steps (Fig. 1, see details in 2.1–2.11), and these are far from efficient. In mammals, only a small fraction (1–10%, depending on the species) of blastocysts derived from somatic donor nuclei develop to term, and even fewer reach adulthood.

True ''clones'' can be produced by methods other than NT as well: splitting embryos into two to four pieces can result in identical twins, triplets, or quadruplets; however, high number of identical animals cannot be obtained by this method. In mouse, from embryonic stem (ES) cells, identical genetically progeny can be obtained when diploid ES cells are mixed with tetraploid embryos. In that case, the diploid cells form the fetus

and the tetraploid cells almost exclusively contribute to the placenta formation. This method is applied in mouse genetic manipulations (Fig. 2), and the outcome is similar to that of the nuclear transfer procedures. The present chapter will focus exclusively on the NT methods.

In the biomedical field, therapeutic cloning combined with the recent progress in human ES cell technology might offer new treatments for various diseases. Xenotransplantation in human medicine using pig organs would rely on cloning technology as well, increasing the research efforts in this species. The potential for cloning in agricultural applications is substantial, and cloned cattle were sold in several countries for breeding and production purposes. In some countries (e.g. Japan), these animals can enter the food chains, although in most other countries concerns about the safety of such animals might result in lengthy investigations before applications. Endangered breed and species preservation might also include cloning technology among the supporting technologies. Transgenic research also profited from the NT technology via the generation of transgenic and knockout farm and laboratory animals from somatic cells. The

future of the nuclear transfer technology depends on a major increase in efficiency, reliability, and safety of the technology.

This chapter discusses in detail the most relevant elements of the NT technology, including the state-of-the-art methodology, the limiting factors, ethical aspects, and the future of cloning.

2 Key Elements and Critical Aspects of the Technology

2.1 Nuclear Reprogramming and Epigenetics

The success of cloning adult animals from differentiated somatic cells has unequivocally disproved the idea that mammalian somatic cell differentiation is irreversible and terminally differentiated cells can no longer transdifferentiate into another cell type or become totipotent again.

The process of returning a differentiated somatic nucleus to a totipotent stage is termed *nuclear reprogramming*. Genes inactivated because of cell differentiation are subjected to reactivation, allowing the reconstructed, cloned embryos to support development and generation of all tissue types in the cloned individual. The inactivation of genes during cell differentiation is believed to involve epigenetic modifications of chromatin. Epigenetics is defined as nuclear inheritance, which is not based on differences in DNA sequences. It involves differential DNA methylation, posttranslational modifications of DNA-binding proteins (e.g. histone acetylation and methylation), and placement of chromatin-binding proteins (e.g multimeric complexes of polycomb- and trithorax-group proteins) to keep chromatin in an active or repressed configuration. These epigenetic signals are stably transmitted during cell division, but are reset in each generation in the gonads during fetal development. Most epigenetic signals are not inheritable from one generation to the next, but are stably maintained within the generation (with some exceptions of transgenerational epigenetic inheritance). In the following section, two of the best-studied epigenetic mechanisms are discussed.

2.1.1 DNA Methylation

In the mammalian genome, the cytosine residue (C) 5′ to a guanine residue (G) can be methylated by DNA methyl transferases and becomes ^{m}CpG (p = phosphate). The methylation pattern of DNA is maintained during cell replication (Fig. 3) by the primary DNA methyl transferase, Dnmt1, which is responsible for the transferring of the methyl group to the semi-methylated, newly replicated DNA (Fig. 3a). DNA elements that contain clusters of CpGs and have a range longer than 500 bp are called *CpG islands*. CpG islands are present in the promoter regions of most housekeeping genes and in imprinted genes, and are often associated with active transcription. DNA methylation plays a critical role in transcriptional repression, during tissue differentiation, allelic specific expression of imprinted genes, and silencing of parasitic retrotransposons. In natural reproduction, DNA methylation undergoes major changes during early development. Shortly after fertilization, a rapid loss of methylation occurs in the DNA of the paternal origin (sperm DNA), which occurs in the absence of transcription or DNA replication and is thus termed *active demethylation*. Thereafter, stepwise decreases in DNA methylation occur in the early embryos until the morula stage, as a result of the absence of functional Dnmt1.

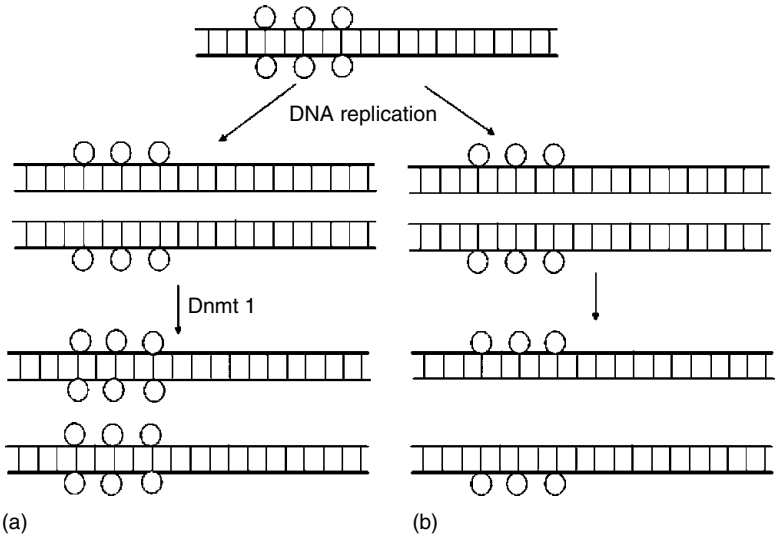

Fig. 3 Schematic illustrations of DNA methylation maintenance and passive demethylation. During DNA replication, the newly synthesized strand (thin line) of DNA will be methylated (ovals) by DNA methyl transferase, DNMT1, in the hemimethylated DNA according to the template of the mother strand (thick line, a). In the absence of functional DNMT1, the newly synthesized DNA strand will remain unmethylated (b). In the next cycle of DNA replication, half of the DNA will be completely unmethylated.

This renders the newly replicated DNA strand devoid of methylation, and the overall level of DNA methylation declines. This replication-dependent demethylation is referred to as *passive demethylation* (Fig. 3b).

In natural reproduction, relatively low levels of DNA methylation exist in the male and female gametes, which are further demethylated during early embryo development. With nuclear transplantation, the somatic nucleus carries the specific epigenetic modifications of its tissue type, which must be erased during nuclear reprogramming. Failure to erase and reestablish epigenetic marks will lead to a lack of embryo totipotency and affect further differentiation and development. Therefore, the levels of epigenetic modification existing in donor cells may affect their reprogrammability following NT. A discrepancy in reprogrammability has been observed in different cell types, which results in altered *in vitro* and *in vivo* development of cloned embryos. Furthermore, treating donor cells with pharmacological agents to remove some epigenetic marks prior to NT may improve the ability of the donor cells to be fully reprogrammed by the recipient karyoplast.

In bovine and other species, embryos cloned from somatic cells showed abnormally higher levels of DNA methylation than control embryos. In these studies, however, either the repetitive regions of the genome or the global methylation of the entire embryo were studied. The global methylation of cloned embryos also is mainly reflective of the methylation levels of the repetitive regions of the DNA. In naturally reproduced animals, repetitive regions of the DNA are normally hypermethylated, and it is unclear

whether hypermethylated repetitive DNA causes abnormal development of cloned embryos. The DNA methylation levels of specific imprinted genes, however, were found hypomethylated in cloned sheep and cloned mouse embryos. In contrast to DNA hypermethylation of cloned embryos, reduced genome-wide DNA methylation levels were found in aborted bovine cloned fetuses, implying that survivability of cloned cattle may be closely related to global methylation losses.

In summary, both global and gene-specific DNA hypermethylation and/or hypomethylation have been associated with cloned embryos and aborted cloned fetuses, suggesting that the reprogramming of epigenetic marks is aberrant using the current NT technology.

2.1.2 Histone Acetylation

Closely associated with DNA methylation is acetylation of nucleosomal histone molecules. Specifically, histone H4, H3, and H2B can be acetylated at numerous lysine residues especially, at lysine 8, 18, and 20, respectively. Acetylated histones in chromatin are also associated with increased gene expression. Evidence suggests that a threshold level of histone acetylation is required to unfold higher-order chromatin structures and facilitate gene transcription. In amphibians, failure of histone deacetylation results in block in embryonic development. In mouse, hyperacetylation is associated with strong zygotic genome activity.

There are two main epigenetic phenomena that are relatively well characterized. Both involve DNA methylation and histone acetylation changes. They are genomic imprinting and X chromosome inactivation (XCI, in females only; see further details below). Both have been active areas of study in somatically cloned animals because somatic cloning bypasses the natural process of parental specific erasure and reestablishment of epigenetic signals (occurs in the gonads). Cloning thus provides an excellent model to investigate whether and how erasure and reestablishment of epigenetic marks occur. Clones of the same donor provide unique experimental materials in that they are genetically identical, yet epigenetically different, at least so far as imprinted and X-linked genes are concerned. This animal model provides insights into epigenetic regulation that cannot be studied by models from natural reproduction, thus revealing unique features of epigenetics not possibly shown previously. A thorough understanding of epigenetic reprogramming in cloned animals will also improve the young and promising technology of cloning by revealing the ideal conditions for a complete reprogramming of the somatic nucleus.

2.1.3 Imprinting and Imprinted Genes in Cloned Animals

Earlier transplantation experiments in the mouse have established that both the maternal and paternal genomes are essential for normal embryonic development. The distinct maternal and paternal contributions are mediated by genetic imprinting, an epigenetic mechanism by which the monoallelic expression of these genes is dependent on whether they are inherited from the mother or the father. Most imprinted genes are involved in fetal growth regulation. To date, more than 40 imprinted genes have been identified, and they code for proteins as well as conserved untranslated RNAs. Examples are insulin-like growth factor 2 (*IGF2*), a paternally expressed fetal specific mitogen, and *H*19, a maternally expressed untranslated RNA

believed to be important in the regulation of *IGF2* imprinting.

Disturbance of normal imprinting (biallelic expression of imprinted genes) as seen in human patients with uniparental disomy (chromosomes or chromosomal regions derived from one parent) can result in severe developmental abnormalities. In mice, experimentally created disruptions in several imprinted genes/chromosomal regions result in embryonic or fetal lethality.

Expression of imprinted genes has been examined in a number of studies in cloned mouse embryos as well as cloned calves or mice. Cloned animals often show signs of imprinting disruptions/disturbance. Various degrees of abnormal levels of expression of several imprinted genes in fetuses and placentas have been observed in ES cell–cloned mice. However, when stem cells are used for nuclear transfer, it is possible that the widespread dysregulation of imprinted genes in these clones may have resulted from the use of stem cells whose DNA is almost totally demethylated. In mice cloned from somatic cells, it was found that the expression pattern of imprinted genes in the donor cells were faithfully transmitted to cloned animals. The levels of expression of imprinted genes, however, were abnormal. Others found striking disruptions in total transcript abundance, allele-specific expression of five imprinted genes examined compared to *in vivo* produced embryos. Only about 4% of cloned embryos recapitulated a blastocyst mode of expression for all five genes studied. Cloned embryos also exhibited extensive loss of allele-specific DNA methylation at the imprinting control regions of the *H*19 and *Snrpn* genes.

Since many of the developmental defects in cloned animals (see details below) are analogous to experimentally created imprinting disruptions in mice and naturally occurring imprinting diseases in humans, this suggests that imprinting disruptions are being introduced by nuclear transfer. Indeed, it was reported that the majority of deceased cloned full-term calves have disruption of imprinting of H19 (biallelic expression). In cloned fetuses derived from donor cells of a bovine interspecies hybrid (*Bos gaurus X B. taurus*), however, normal allelic expression of *Igf2* and *Gtl2* (Gene trap locus 2) in Day 40 bovine cloned fetuses and placentas was observed. Because cloned mice from genetically heterozygous F_1 mice survive better than those cloned from inbred mice, it is possible that this may also be true in the bovine and that the normal imprinting patterns found in this case might have reflected those from surviving clones of highly heterozygous background.

Expression abnormality of imprinted genes may be due to incomplete and aberrant reprogramming of epigenetic marks already existing in the donor cells.

2.2 Epigenetic Differences between Donor Cells

The first step in cloning and a major source of experimental variation is choosing a nuclear donor. On the basis of the donor cell epigenetic status, there are two broad categories of cloning: **embryonic cloning**, encompassing blastomeres, ES, and germ cells as donors, and **somatic cloning**, using somatic cells of varying differentiation status from fetal, newborn, or adult sources. Normally, epigenetic differences are very stable. Differentiated cells do not easily switch from one cell fate to another. It requires radical experimental manipulations, such as NT, to force them to change their cellular identity

and differentiation status. The success of cloning decreases as donor cells differentiate, thus embryonic cloning is generally much more efficient than somatic cloning. The following section describes, in order of increasing differentiation, the range of donor cell types that have been used for NT, and evaluates their usefulness for cloning.

2.2.1 **Embryonic Cloning**

Blastomeres After fertilization, the zygote cleaves into progressively smaller nucleated cells, called *blastomeres*. In mammals, individual blastomeres are phenotypically equivalent and totipotent (able to give rise to all embryonic and extraembryonic cell types), at least up to the 8-cell stage. Thereafter, the reduced size of the resulting embryo makes it technically difficult to assess their full developmental potential. Blastomeres were the first cells to be used in cloning amphibians. Similarly, all initial successes in mammalian cloning were achieved with nuclei from early-cleavage-stage embryos (8–16 cells) of sheep and cattle. Following NT, there is a progressive restriction in the developmental potency from the 1-cell stage onward, which is reflected in decreasing rates of cloned embryo development after NT of 2-, 4-, and 8-cell blastomeres into enucleated metaphase II (MII)–arrested oocytes, zygotes, or 2-cell blastomeres as recipients (Fig. 4). Cloning efficiencies with such

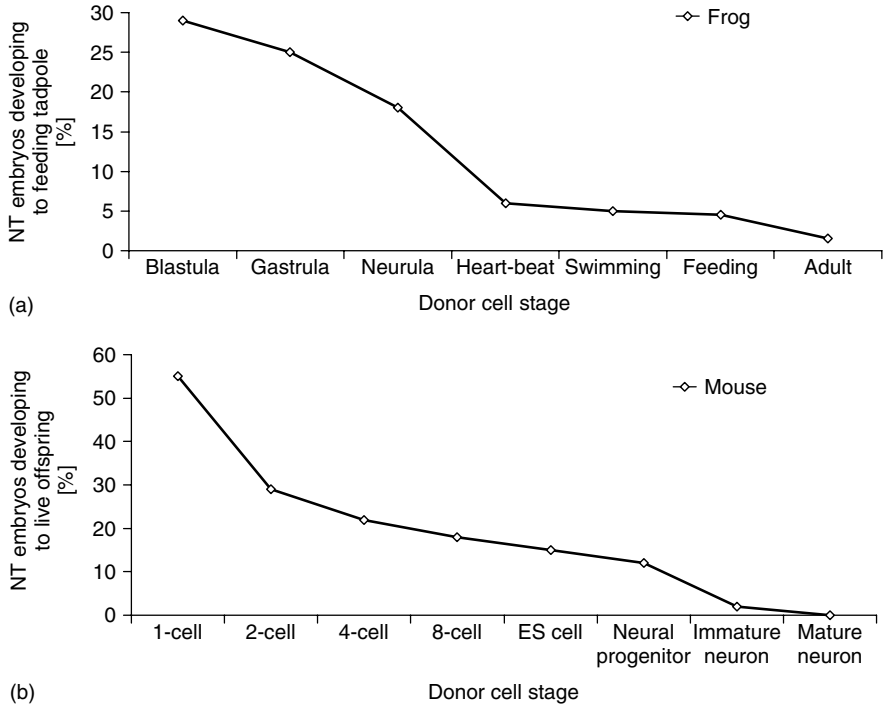

Fig. 4 Cloning efficiency declines with increasing donor cell differentiation in both frogs and mice. (a) Tadpoles advance from heartbeat to swimming to feeding stages before metamorphosis into adults. (b) Neural progenitors and immature neurons were isolated from the embryonic and mature neurons from the adult cerebral cortex, respectively.

early-cleavage-stage donor cells are much higher than with somatic cells. For example, metaphase-arrested 4-cell-stage donor nuclei are one order of magnitude more efficient in generating live mouse clones than metaphase-arrested fetal fibroblasts (43% vs 3%), using the same serial NT (see below) technique. Morula formation (8-cell stage in mouse, 32-cell stage in cattle/sheep) marks the beginning of cellular differentiation during preimplantation development, eventually leading to the foundation of the trophectoderm and inner cell mass (ICM) lineages from the outer and inner cells of the morula respectively. Donor cells derived from such later preimplantation stage embryos result in progressively lower cloning success. However, compared to somatic cells, bovine morula blastomeres still are about sixfold more efficient (28% vs 5%). Fresh ICM cells were first successfully used in sheep and cattle, soon followed by cloning from short-term bovine ICM cultures. In mouse, successful cloning from ICM and trophectoderm cells required serial NT and revealed no differences in cloning efficiencies between these two cell types (11% vs 8%). Although abnormal phenotypes are still observed with blastomere cloning (e.g. oversized fetuses and higher perinatal loss), the incidence and severity are greatly reduced. The high success rates with blastomere donors is likely due to blastomeres retaining an epigenotype that is more compatible with early embryonic development.

Embryonic stem cells ES cells are immortal pluripotent (able to give rise to all cell types of the embryo proper) cells derived from placing ICM blastomeres into *in vitro* culture. It is still unclear if ICM cells are homogeneously pluripotent, and if ES cells derive from a definable and functionally identical pluripotent ICM cell or subpopulation of cells that exists within the blastocyst prior to ES cell isolation and culture. *Bona fide* ES cells, defined as being capable of generating germ line chimaeras, are only available from a few mouse strains, and all attempts to derive such ES cells from livestock embryos have failed so far. However, long-term ''ES-like cell'' cultures in farm animal species show extensive *in vitro* differentiation ability or demonstrate somatic cell chimerism. Some of these cells resemble murine ES cells in both morphology and antigen profile and remain pluripotent in culture after 150 passages. Cloning efficiencies with murine ES cells are similarly remarkable as with blastomeres (10–20% vs 1–3% with fibroblasts, Sertoli, or cumulus cells) and probably for the same reasons. Like the ICM blastomeres they are derived from, ES cells retain an epigenotype that is more compatible with early embryonic development and does not need extensive reprogramming. Candidate gene expression profiling shows that all ES cell–derived blastocysts faithfully express key embryonic genes such as the transcription factor Oct4 and related sequences that are present in the pluripotent cells of the early embryo, whereas 38% of cumulus-cloned blastocysts fail to reactivate these genes.

The major problem with ES cell donors compared to blastomeres is their extreme epigenetic instability in long-term culture. DNA-methylation patterns and expression of imprinted genes vary widely between ES cell lines, between subclones of a given ES cell line, and even between individual cells of a given ES subclone after *in vitro* culture. Mice cloned from either single cells (via NT) or several cells (via tetraploid embryo complementation, see Fig. 2) of a particular ES subclone show

substantial variation in gene expression. This can be explained by epigenetic changes among daughter cells derived from the original single-cell clone. It makes it difficult to distinguish whether the observed widespread dysregulation of imprinted genes in ES cell–derived cloned mice is due to reprogramming errors or solely due to preexisting epigenomic errors in the ES donor cells.

Primordial germ cells In mammals, the germ cell precursors – the primordial germ cells (PGCs) – can be identified for the first time in the gastrulating embryo. PGCs have characteristic epigenomic modifications that distinguish them from all other cells. These include extensive genome-wide demethylation, leading to erasure of allele-specific methylation of imprinted loci and reactivation of the silent X chromosome. PGCs are probably the only mammalian cells where both parental genomes are functionally equivalent. The absence of imprints results in either biallelic expression or repression of specific imprinted genes. Contrary to previous expectations, cloning from imprint-free PGCs did not generate viable offspring, but resulted in developmental arrest at early postimplantation stages and abnormal placental development. This phenotype was consistent with a complete lack of gene dosage regulation for imprinted genes. Cloned embryos derived from meiotically arrested nongrowing female germ cells displayed similar dysregulation of gene expression and did not progress beyond the 8-cell stage. In frogs, PGC nuclear donors can support development to metamorphosis stages, consistent with the notion that global demethylation, imprinting, or inactivation of sex chromosomes is not evident in amphibian species.

Embryonic germ cells When PGCs are cultured *in vitro*, they transform into immortal pluripotent embryonic germ cells (EGCs). Their developmental potential is so similar to ES cells that their different origin is sometimes ignored and both are collectively referred to as *ES cells*, even though they differ in their expression of some imprinted genes. *Bona fide* EGCs are only available for mouse and humans, and no EGCs capable of generating germ line chimaeras have been reported from livestock animals. Previous studies have shown that they share a similar epigenotype with the PGCs they are derived from and undergo comparable epigenetic changes. Consequently, imprint-free EGCs are likely to result in the same problems previously encountered with cloning from PGCs. The epigenetic stability of EGCs compared to ES cells has not been thoroughly investigated and will depend on their DNA-methylation status at the time of isolation.

2.2.2 Somatic Cloning

The first four decades of NT experiments were dominated by the idea that cloning success depended on the donor cell being somehow embryonic in nature. This notion was supported by data from amphibian cloning, where NT with adult cells had only given limited success and never resulted in adult frogs cloned from adult somatic donor cells. However, previous preconceptions changed radically with the first successful cloning of sheep from an established embryonic cell line in 1995. This cell line was derived from culturing differentiated embryonic disk cells over several passages and did not resemble any of the previously described ES cell–like lines. This success suggested that cloning from more differentiated, even adult, somatic cells might be imminent. In 1996,

the birth of Dolly, cloned from a mammary gland cell, proved this prediction to be correct and triggered a renaissance of adult somatic nuclear transfer. Since then, numerous studies comparing various differentiated somatic donor cells types have been undertaken in frog, mouse, and cattle. As with embryonic blastomeres, the ability of somatic nuclei to promote normal development after NT decreases as donor cell differentiation increases.

Adult stem cells The mechanisms governing the segregation into a germ line and a soma line are commonly associated with restriction of cell potency in somatic cells, but this may not be universally true. Adult stem cells are defined as undifferentiated multipotent (able to give rise to a subset of cell lineages) cells capable, at the single cell level, of proliferation, self-renewal, and the production of differentiating daughter cells. They have been described for the adult bone marrow, nervous system, skin, muscle, and intestine where they are thought to be responsible for regenerating damage and maintaining homeostasis. Some adult stem cells may even be capable of differentiating across tissue lineage boundaries; however, studies proposing such apparent ''lineage plasticity'' remain controversial. Owing to the lack of exclusive phenotypic markers, adult stem cells are much more difficult to isolate and purify than ES cells; however, it is only a question of time until their applicability for cloning will be explored. Future NT experiments may also help to better define the epigenomic status of adult stem cells.

Progenitor cells Stem cells produce progenitor or precursor cells as a lineage progresses down its differentiation pathway. Progenitors are operationally defined as transiently proliferating oligopotent (able to give rise to a restricted subset of cell lineages) or unipotent (able to contribute only one mature cell type) cells that have passed the critical transition point of commitment to one or multiple lineages. Freshly isolated neural progenitors from the ventricular side of the cerebral cortex of mouse fetuses have resulted in considerably higher cloning efficiencies than any other somatic cell type in this species, (12% vs 2% with putative embryonic neurons and commonly used fibroblasts or cumulus cells), indicating that these cells may be more amenable to epigenetic reprogramming than their differentiated progeny.

Terminally differentiated cells In animals, more than 200 distinct cell types are plainly distinguishable by morphology, and more will probably be discovered when better molecular markers become available. Less than 10% of these have been tested as nuclear donors and many repeatedly failed to generate viable offspring. In frog, live offspring surviving into adulthood were obtained only with larval intestinal epithelial cells. In mouse, live offspring were obtained after NT with fibroblasts from various different tissues (skin, liver, muscle, and gonads), Sertoli, and cumulus cells. Most cell types repeatedly failed to develop after implantation, including macrophages, spleen, and brain cells. In cattle, live offspring were obtained from follicular and oviduct epithelial, mammary gland, skin, liver and muscle fibroblasts, and blood leukocytes.

One problem in somatic cloning is the lack of accurate donor cell identification. Presently, the most commonly used somatic cells are of the morphologically defined ''fibroblast-like'' phenotype.

Fibroblasts are dispersed in connective tissues throughout the body and are capable of extensive proliferation, tissue repair, and differentiation into a variety of other connective tissue cells. None of several molecular fibroblast markers, such as vimentin and FSP1, have been proven highly specific. Reliable molecular markers to distinguish between immature and mature fibroblasts or fibroblast lineages are rare. Lung fibroblasts, for example, fall into at least two subpopulations that differ in growth rate, morphology, and antigen expression. Clearly, cell lines isolated from whole fetuses and loosely termed fibroblasts on the basis of morphology are a population of mixed lineages. Leukocytes, cumulus, and Sertoli cells are better defined in terms of their origin, distinct morphology, and surface marker expression. The best-defined donor cells to date are genetically marked mature B and T lymphocytes and olfactory neurons in mouse. Fertile adult mice were derived from both these donor cell types, demonstrating unequivocally that the nuclei of terminally differentiated cells can be reprogrammed to a totipotent state. However, in both cases, cloning success required an indirect two-step procedure, whereby somatic cell NT first generates cloned blastocysts, from which ES cells are derived for injection into tetraploid host blastocysts in a subsequent round of cloning (tetraploid complementation). In this approach, the embryo is derived entirely from the ES cells, whereas the placenta is derived from the tetraploid host cells. The standard approach of directly transferring NT embryos into recipient females repeatedly failed, suggesting that cloning from terminally differentiated cells might be extremely inefficient.

Differentiated cells can remain mitotically active or postmitotic. There is no obvious correlation between natural exit from the cell cycle and cloning competence. For example, fibroblast and immature Sertoli cells are highly proliferative, whereas cumulus cells are a naturally quiescent subpopulation of ovarian granulosa cells. Cloning efficiencies for both cell types are similar.

For any given somatic cell type, the best source of cells for NT is still a matter of debate. For example, skin fibroblasts have been isolated from fetal, newborn, or adult sources with either no difference in cloning efficiencies or fetal sources achieving higher efficiencies than adult ones (13% vs 5%). For some agricultural applications, such as cloning of progeny-tested bulls, the source of donor cells will usually be restricted to easily accessible adult tissue. For transgenic applications, where the cells undergo time-consuming selection steps and extensive propagation *in vitro*, it may be beneficial to use cells from fetuses or calves since they have a longer proliferative life span before reaching replicative senescence. Cells after long-term culture or near the end of their replicative life span do not result in significantly reduced cloning efficiencies compared to fresh or short-term culture cells.

2.3 Genetic Differences between Donor Cells

Genomic non-equivalence Viable nuclear clones provide the most complete experimental evidence for genomic equivalence, that is, the concept that the DNA in every somatic cell nucleus of an individual is identical and contains all the information for the development of a new organism. Only in a few cases does cell specialization involve detectable loss of genetic material.

In mammals, red blood cells are an extreme example as they lose their entire nucleus. B and T lymphocytes eliminate a portion of their genome during differentiation; despite this, following NT, they can develop into blastocysts and term pregnancy. It is not known whether the very low frequency of further development from such cells is related to their genetic rearrangements.

Gene damage For cloning to work, the donor genome must probably be intact. It is assumed that in amphibians chromosomal abnormalities resulting from incomplete replication after NT account for all cases of early embryo losses. The same problem arises when donor cells have not completed DNA replication before NT. Continuous cell lines often show karyotypic alterations, in particular, for negative cell cycle regulators, and embryos reconstructed with spontaneously immortalized bovine mammary gland cells failed to develop to blastocysts, even though 86% showed a normal diploid karyotype. NT embryos derived from granulosa cells with high levels of aneusomy produce significantly more embryos with karyotypic errors than those from fibroblasts with fewer chromosomal anomalies or IVF-controls embryos. Evidently, such donor-derived chromosomal anomalies can substantially affect cloning success, emphasizing the need for rigorous prescreening of donor cells before NT. Higher aneuploidy has also been observed in cloned blastocysts derived from karyotypically normal granulosa cells, indicating that they can be introduced by the NT procedure itself.

Each nuclear gene is inevitably subject to a small risk of spontaneous mutation at an estimated rate of about 10^{-6} mutations per gene per cell division. Therefore, in the absence of mutagens, the chances of mutating both copies of an essential gene *in vivo* are extremely small. Theoretically, cells from some tissues may be more prone to suffer from DNA damage. Skin, for example, is more susceptible to UV-induced damage; however, ear skin fibroblasts from a 17-year old bull have been successfully used in cloning. Likewise, there is no evidence that accumulating mutations during aging and/or time *in vitro* affect cloning efficiencies. Cells after long-term culture or near the end of their replicative life span did not have significantly reduced cloning efficiencies compared to short-term culture cells.

The mutation rate in mitochondria is 10 to 20 times greater than that in nuclear DNA with some components mutating up to a 100 times more rapidly, and this may contribute to potential problems with mitochondrial heteroplasmy.

Mitochondrial heteroplasmy During normal development, genetic material outside the nucleus could in principle be inherited through both the cytoplasm of the recipient oocyte and the sperm. Mitochondrial DNA (mtDNA) in mammals, however, is exclusively maternal in origin. The sperm contributes up to 100 functional mitochondria at fertilization, which is less than 0.1% of the total number present in the egg cytoplasm. All paternal mitochondria are selectively destroyed during early cleavage stages. Destruction depends on the ubiquitination of sperm mitochondrial membrane proteins during spermatogenesis. This posttranslational modification marks them for subsequent proteolysis by the lysosomal machinery of the developing embryo. The exact evolutionary and developmental advantages of this elimination process are unknown.

Depending on NT method and donor cell type, a variable number of foreign mitochondria is initially introduced into the oocyte during cloning. Strictly speaking, cloned animals are therefore only genetic duplicates of the donor nuclear genome used for NT. At later stages some, but not all, cloned animals show low levels of mitochondrial heteroplasmy, that is, the presence of more than one type of mtDNA within a cell.

In principle, this observed heteroplasmy could result in pathologies if either the introduced mtDNA carries deleterious mutations or if the presence of intact foreign mtDNA per se somehow interferes with cell survival due to incompatibility between nuclear and different mitochondrial genomes.

In humans, more than 100-point mutations and numerous large-scale deletions have been associated with various diseases that frequently manifest themselves in tissues with high metabolic demands, such as brain and muscle. This clinical phenotype is inconsistent with the major phenotypes observed in clones. Conclusive evidence that the presence of intact foreign mtDNA alone is sufficient to impair development is also lacking. Even the assumption that most organisms are homoplasmic may be overestimated. Natural heteroplasmy occurs, indicating that the tolerance to multiple mitochondrial genotypes is higher than previously thought. Consequently, cross-subspecies and species cloning has proven to be a viable approach in cattle, sheep, and some Felidae. In conclusion, the link between heteroplasmy and cloned-offspring syndrome remains largely speculative.

Intriguingly, some incompatibility problems can even arise in homoplasmic animals. Nucleocytoplasmic hybrids between different mouse strains have shown alterations in the adult phenotype. Strikingly, these changes are transmittable through the germ line. Mismatches in the complex interactions between recipient mitochondrial genes and their complementary partner genes in the donor genome may account for the observed phenotype. These experiments emphasize the need for matching genetic background between donor cell and recipient oocyte in cloning experiments.

Genetic background Among cloned mammals so far, only mice offer the advantage of a defined genetic background. There are many inbred strains available and F1-crosses can readily be obtained. The highest cloning efficiencies were achieved with oocytes and donor cells of hybrid mice. Somatic nuclei from inbred mice (except the 129/Sv strain) seldom supported postimplantation development. Both postimplantation and postnatal viability improved dramatically when F1 ES cells, instead of inbred or out-crossed ES donors, were used. Remarkably, all mice derived from ES cells of several inbred strains died at birth from respiratory failure. Hybrid mouse embryos also perform much better in culture than inbred strains. The beneficial effect of hybrid vigor or heterosis is a well-known phenomenon in animal breeding. F1-animals are maximally heterozygous for all genetic loci, especially when they come from two inbred strains. Similarly, hybrid recipient oocytes have an advantage over homozygous oocytes in supporting *in vitro* development of cloned embryos, at least in certain culture media.

Telomeres Telomeres are protective structures (copies of a hexamer repeat sequence (5′TTAGGG3′ in human) and associated proteins) that ''cap'' the ends

of mammalian chromosomes and prevent repair mechanisms that would result in end-to-end chromosomal fusions. In the absence of telomerase (the primary enzyme that is capable of adding telomeric DNA to the end of chromosome) activity, they progressively shorten as a consequence of cell division. Telomere shortening correlates with cellular aging of human fibroblasts *in vitro*, and may play a role in the induction of replicative cell division arrest in the G_1 phase of cultured human cells, a state known as *senescence*. Some cells isolated from older individuals have a shorter replicative life span in culture and shorter telomeric DNA, which has been taken as evidence for a role of telomere shortening *in vivo*. However, the correlation between telomere length and aging is dependent on cell type, species, and culture conditions. Mouse cells have comparably long telomeres (≈60 kb), show telomerase activity in many tissues, and reach replicative senescence well before detectable telomere erosion (after 15–30 doublings in culture). Humans have shorter telomeres (≈12 kb), no telomerase activity in most tissues, and therefore telomere shortening may limit the longevity of human cells in culture. In cattle, average telomere length (≈20 kb) was shown to decrease with age and time in culture for both fibroblasts and very late passages of ES-like cells. Bovine ES-like cells show higher telomerase activity than fibroblasts, and, for both cell types, early passages show higher telomerase activity compared to late passage cells. More importantly, it has not been convincingly demonstrated whether cellular senescence occurs *in vivo* and whether such a process would then have anything to do with organismal aging. If this was the case, cloning from adult cells could result in offspring with shorter telomeres, premature onset of aging, and a reduced life span.

The dynamics of telomerase activity during early embryo development was extensively studied in cattle. Telomerase activity is found upregulated at the blastocyst stage in nuclear transfer systems similar to that of *in vitro* fertilized embryos. The upregulating of telomerase activity at the blastocyst stage may contribute to telomere length restoration in embryo development after nuclear transfer and could explain the normal telomere length found in some cloned animals, including cattle and mice.

In contrast, Dolly, the sheep, had shorter telomeres and calves cloned from a 10-year old bull had similar or even shorter telomeres than the donor animal, apparently depending on the cell type investigated. The latter report also describes an ''adult'' phenotype (e.g. wrinkled skin, thick bones, and rough hairs) of the cloned male calves, in contrast to clones from a 17-year old bull, which appeared phenotypically normal.

Donor cell effect on telomere length was described in cattle, using nuclei of donor cells derived from muscle, oviduct, mammary gland, and ear skin. All three types (normal, shorter, longer) of telomeres were found when different donor cell types were compared. Clones from muscle or ear skin cell origin had longer telomeres than the donor animal, but were within the normal range of same age controls. Clones from oviduct and mammary epithelia cell origin had telomeres that were shorter than those of controls, while clones derived from embryonic cell origins have telomeres longer than those of their age-matched controls. The time cells spend in culture might affect the process: senescent cultured bovine fibroblasts with shortened telomeres were used as nuclear donors in a

Lazarus-type experiment, whereby the resurrected donor cells, after NT, displayed even longer telomeres than age-matched controls and increased proliferative life span in culture. Similarly, in sheep, it has been shown that NT did extend the telomeres from donor nuclei derived from late-passage cells that are near senescent (maybe by repair mechanisms triggered); however, in fetuses generated from early passage donor cells, telomeres were not significantly different in length to those in the donor cells.

One difficulty in interpreting the conflicting data is the significant telomere length variation among and within individual cloned and control animals. Ideally, telomerase activity and telomere length should be compared between donor cells and cloned cells of the same type and age and cultured under exactly the same conditions. In summary, telomerase reactivation and telomere length adjustment can be accomplished after NT; however, potential effects on overall longevity of cloned animals still need to be determined in long-term studies.

X chromosome inactivation In mammals, males have one, while females have two copies of the X chromosomes. This creates a situation in which there is an unequal gene dosage among males and females. During evolution, this was solved by a process termed *X chromosome inactivation* (XCI), the random transcriptional silencing of one of the two X chromosomes in somatic cells of females during early development. XCI occurs by the process of epigenetic modification, the inactivated X chromosome is hypermethylated in DNA and hypoacetylated on histones. Proper XCI is essential to embryonic development. Inactivation of both X chromosomes in mouse embryos leads to embryonic lethality, and having more than one active X chromosome is deleterious to extraembryonic development and also causes early embryonic death in mice.

X chromosome inactivation occurs at late blastocyst stage in mice. Before fertilization, the egg carries an active X chromosome that is of maternal origin (X_a^m), while the sperm carries an inactive X of paternal origin (X_i^p). At the formation of the female zygote, both X chromosomes become active ($X_a^m X_a^p$). This state of activation persists through early blastocyst stage. During late blastocyst stage, the expression of the X-inactivation specific transcript (*Xist*) gene from one of the two X chromosomes, in a random fashion in the inner cell mass, leads to its inactivation (X_i). In extraembryonic tissues, however, the paternal X chromosome is preferentially inactivated in the mouse, resulting in imprinted XCI. Once established, the inactive state of a particular X chromosome is epigenetically inherited throughout all subsequent cell divisions.

In somatic cloning through nuclear transfer, the cloned zygotes receive one active (X_a) and one inactive (X_i) X chromosome from the donor cells (Fig. 5). This state of X inactivation is different from that in naturally fertilized female zygotes, in which both X are active. During nuclear reprogramming, it is unclear whether the inactivated X is reactivated or the pattern of XCI in the donor cell is maintained in the cloned animals. The first study of XCI reprogramming in cloned animals reported that epigenetic marks on the somatic X chromosomes in mice were completely erased and then appropriately reestablished by the nuclear reprogramming process, leading to normal random XCI in the cloned embryos. Using female donor cells with genetically marked X chromosomes, it was demonstrated in

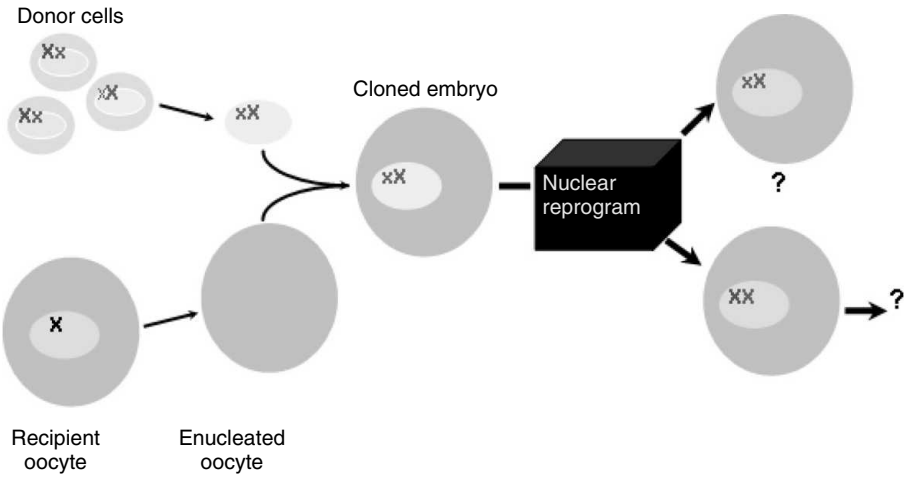

Fig. 5 Question of reprogramming of X chromosome inactivation in cloned embryos. During nuclear transfer, a somatic cell with preexisting active and inactive X chromosomes is transferred into an enucleated oocyte. After nuclear reprogramming, which is still largely a black box, it is unclear whether the inactivated X will become reactivated to result in two active X as in the naturally fertilized zygote, or the pattern of XCI of the somatic donor cell will be maintained in the cloned animal.

cloned mouse embryos that X chromosomes are initially reactivated in most or all blastocyst cells, and, subsequently, either randomly inactivated in the embryo proper or nonrandomly inactivated in the trophectoderm. The X_i in extraembryonic tissues was not always the paternal one (as during normal embryogenesis), but was determined by the status of X inactivation in the somatic donors, suggesting some functional equivalence between the imprinted paternal or maternal X and the inactive or active somatic X, respectively. Thus, the process of X inactivation was recapitulated at least in the few surviving blastocysts, female fetuses, and offspring.

In cattle studies on XCI by following the allele-specific expression of the X-linked housekeeping gene monoamine oxidase type A (*MAOA*), it was found that, as in the mouse, XCI in cattle somatic cells is also random and in placenta is paternally imprinted. In cloned calves that died shortly after birth, however, expression of both alleles of the *MaoA* gene was observed, suggesting aberrant XCI. Furthermore, inactivation of both alleles of several X-linked genes was also observed in organs of several deceased clones. Interestingly, the transducin (beta) like 1 (*TBL1*), a gene known to escape XCI in humans and mice, was expressed in all organs of these clones. Consistent with observations of aberrant XCI in internal organs, random XCI in the placenta of all deceased clones examined was found. Placental abnormalities have been reported in both live and deceased cloned calves.

The aberrant XCI in bovine clones may have resulted from incomplete erasure of the epigenetic marks on the X chromosomes of the somatic donor cells during nuclear reprogramming, which in turn may lead to only partial reactivation of the X_i or to abnormal methylation patterns of

the *Xist* gene in one or both X chromosomes prior to XCI. Upon differentiation, those epigenetic marks already present on the X chromosomes of the cloned embryo may interfere with the ones further imposed during XCI in clone development, ultimately leading to the observed aberrant expression patterns of X-linked genes. The interesting finding that *TBL1*, a gene that escapes XCI, was properly expressed in all clones may indicate that regions of the X chromosomes not subjected to XCI, thus not epigenetically modified, are less affected by events involved in nuclear reprogramming. In summary, reprogramming of the inactivated X chromosome in cloned female animals appears to be different in different species. In any case, faulty reactivation and subsequent nonrandom inactivation would not be a problem for male cells and those 50% of somatic female donor cells with a paternal X_i. Studies comparing the cloning competence of male and female somatic donors found no significant differences using male and female tail-tip fibroblasts, thus demonstrating that abnormal XCI is not the main limiting factor of NT.

2.4 Choice of Nuclear Donor Cell Cycle Stage

2.4.1 The Donor Cell Cycle

The cell division cycle has four distinct phases: G_1, S, G_2, and M. Following mitosis, the daughter cells enter G_1, during which the cells increase in size and respond to extracellular growth factors that regulate the synthesis of G_1 cyclins. The accumulation of active complexes between G_1 cyclins and cyclin dependent kinases (CDKs) results in progression past the restriction point (R-point) of the cell cycle. As cells transit the R-point and the later phase of G_1, they are committed to undergo another round of DNA replication in S-phase. This is followed by accumulation of active complexes between mitotic cyclins and their respective CDKs to pass another checkpoint in G_2 before cells enter mitosis, whereby the replicated DNA is segregated equally to the two daughter cells. This canonical cell cycle can be adjusted to meet special developmental requirements, as in the rapid cycles of cleavage blastomeres with very short gap phases, and the relative importance of different checkpoints may be altered.

In principle, cell cycle coordination between the nuclear donor cell and the enucleated recipient cell (cytoplast) can increase cloning efficiency for two reasons: (1) by maintaining normal chromosome constitution (ploidy) in the reconstructed NT embryo and (2) by promoting epigenetic reprogramming of the donor genome.

2.4.2 Cell Cycle Coordination to Maintain Normal Ploidy

There is ample evidence for the importance of donor-recipient cell cycle coordination to maintain normal ploidy. The ability of donor nuclei to maintain normal ploidy depends on the activity of cyclin B and Cdk 1 (formerly $p34^{cdc2}$) complexes (M-Cdk, formerly maturation promoting factor or MPF) in the cytoplast. In its active form, M-Cdk induces nuclear envelope breakdown, chromosome condensation, and assembly of a microtubule spindle. Metaphase II-(MII) arrested oocytes maintain a high M-Cdk activity that is stabilized by a calcium sensitive cytostatic factor (CSF). After activation, an increase in intracellular calcium inactivates CSF, enabling ubiquitin-dependant degradation of cyclin B through the anaphase-promoting complex which destroys M-Cdk activity.

Therefore, two types of cytoplast may be used for NT: either nonactivated (high M-Cdk) or activated (low M-Cdk).

NT into non-activated cytoplasts When an interphase donor nucleus is introduced into a nonactivated cytoplast, the high M-Cdk activity induces or maintains nuclear envelope disassembly, chromosome condensation, and spindle formation. Following activation, the nuclear envelope reforms around the donor chromatin, which then undergoes a round of DNA synthesis regardless of its previous cell cycle stage. From these general events, three situations can be distinguished, depending on the state of nuclear contents (e.g. amount of DNA) and cytoplasmic contents (e.g. cell cycle regulatory factors, organelles) of the donor cell:

1. *G_0/G_1-phase donor nuclei* G_0 and G_1 are often grouped together as G_0/G_1, although these phases are operationally defined differently. G_0 cells are thought to exit the cell division cycle and enter transient or permanent quiescence, whereas G_1 is the intermediate stage between M- and S-phase in growing cells. However, cells in both phases contain the same amount of chromatin (2N), and their chromosomes are not ready to segregate. As the DNA has not yet replicated, the genome must remain within the reconstructed embryo to stay diploid. Moreover, the organelles (e.g. nuclear envelope, endoplasmic reticulum, and Golgi apparatus) are in their intact interphase configuration; the centriole has not replicated; and M-Cdk is stably inactivated.
   Following NT, the donor chromatids prematurely condense and each attaches, apparently randomly, to a single pole of a newly formed spindle apparatus. After activation, nonhomologous chromosomes segregate and form multiple pseudopronuclei. In mouse, actin-depolymerizing drugs, such as cytochalasin B, are required to prevent cytokinesis and expulsion of a pseudopolar body containing chromatin, which would otherwise lead to nonviable aneuploid embryos. Expulsion of a pseudopolar body is related to the time interval between nucleus introduction and activation. When activation occurs within 5 to 30 min of reconstruction, no polar bodies are extruded and a single diploid nucleus results. However, when activation occurs at least 1 to 3 h later, the majority of NT embryos extrude a polar body. The claims that rabbit and livestock NT embryos do not undergo pseudopolar body extrusion may in part be related to the NT methodologies used in these studies, including the time interval between fusion and activation, and/or possible differences in spindle formation between species.
   Presumptive G_0 cells are obtained by depletion of essential mitogens and growth factors in the culture medium either through serum deprivation or culture to confluency. G_1 cells are obtained by different methods; for example, mitotic selection or drug-induced G_1-phase arrest. Both G_0 and defined G_1 cells have resulted in viable cloned animals.
2. *G_2/M-phase donor nuclei* In the case of G_2/M-phase cells, the donor chromosomes are duplicated (4N), sister chromatid cohesion is established to enable equal segregation; the chromatin is condensed, transcriptionally inactive, and ready to segregate. Moreover, M-phase cells have grown to their maximal

size, the nuclear envelope, endoplasmic reticulum, and Golgi apparatus are dissociated; the centriole has replicated and the mitotic spindle formed; and M-Cdk activity is highest. This is essentially the cell cycle status of the MII oocyte before enucleation and NT. The use of donor cells in M-phase may therefore be maximally compatible with MII cytoplasts.

Following NT, the double-stranded condensed chromatids align regularly on a spindle resembling a metaphase plate. Sister chromatids attach to opposite poles of the spindle and segregate orderly after activation in the absence of cytochalasin B. This is followed by expulsion of a pseudopolar body, removing the extra set of chromatin and resulting in a single, presumably diploid, pseudopronucleus in most reconstructed embryos. This phenomenon may not occur in early G_2 or if the sister chromatids fail to properly align on a spindle (if insufficient time is allowed between reconstruction and activation) or if there is uneven or random segregation. If segregation or expulsion does not occur, then following nuclear envelope reformation, DNA rereplication will compromise ploidy in the NT embryo.

Mitotic somatic donor nuclei cells have been reported to result in viable cloned mice and calves, respectively. G_2-phase somatic donors resulted in viable offspring in mouse, but not in cattle, probably due to difficulties of reliably synchronizing cell in G_2.

3. *S-phase donor nuclei* Depending upon the degree of replication, S-phase nuclei possess anything between 2 to 4N amounts of DNA, and the chromosomes are not yet ready to segregate. Following NT in a high M-Cdk environment, the chromatin of S-phase nuclei typically has a fragmented appearance and high incidence of chromosomal abnormalities. Following activation, the nucleus rereplicates its DNA, resulting in incorrect ploidy and developmental failure.

NT into activated cytoplasts In contrast to the situation above, interphase nuclei transferred to cytoplasts with basal levels of M-Cdk activity, following a sufficient interval after activation, do not undergo nuclear envelope breakdown, and it is the donor nucleus that controls DNA replication in accordance with its own cell cycle stage at the time of transfer. Thus, nuclei in G_1 or S-phase may initiate or continue replication, respectively, while those in G_2 are not induced to enter another round of DNA synthesis. Such preactivated cytoplasts have been termed *universal recipients* and are capable of coordinating the development of donor cells at any interphase stage of the cell cycle, at least in terms of maintaining normal ploidy. This has been especially important for cloning preimplantation-stage embryos, where most blastomeres are in S-phase (80–90%), and are therefore only compatible with transfer to cytoplasts low in M-Cdk. However, somatic cells transferred into cytoplasm low in MPF may not be optimal for reprogramming and embryo development.

2.4.3 Cell Cycle Coordination to Promote Reprogramming

In summary, somatic donor cells in presumptive G_0/G_1 and G_2/M-phase can result in offspring upon transfer into non-activated cytoplasts, whereas S-phase donors cannot. The question remains, however, whether any of the cell cycle

stages compatible with ploidy is superior for epigenetic reprogramming and overall cloning efficiency.

NT into non-activated cytoplasts The first reports describing the production of cloned mammals from differentiated cultured cells claimed that their success was due to the use of serum-starved cells (presumptive G_0-cells). Intriguingly, the failure of earlier studies to generate fertile cloned adults following NT with quiescent cells, for example, nondividing keratinocytes and intestinal epithelium cells in *Xenopus*, terminally differentiated erythrocytes in *Rana*, Day 15.5 male mouse fetal germ cells, and bovine cumulus cells may have been due to other limiting facets of the NT techniques. Shortly after the initial successful reports with quiescent cells, it became obvious that randomly picked donor cells from nonserum-starved cultures (presumptive G_1-cells) were also successfully reprogrammed and resulted in viable offspring following NT in cattle and mice. However, in both cases, the exact stage of the donor cell cycle at the time of NT remained unproven. Later studies directly compared better-defined cell populations (e.g. mitotically selected G_1-with serum-starved or confluent donors) to address the question whether there is an optimal donor cell cycle stage. From these studies, it appears that there is little difference between G_2/M and G_0/G_1, particularly with mice. It is less clear as to the efficiency of G_2/M-phases in livestock, and it is only a suggestion that G_0 is superior to G_1 in cattle.

NT into activated cytoplasts Preactivated cytoplasts with low M-Cdk result in very poor embryo development after NT with somatic cells in either G_0/G_1- or S-phase. It appears that nuclear envelope breakdown may be required in order to allow chromatin remodeling and expose the chromatin to licensing factors enabling initiation of DNA synthesis following NT. Preactivated telophase II cytoplasts have been successfully used with G_0/G_1-donor cells in goats, but these recipients may still contain enough residual M-Cdk activity to disassemble the nuclear envelope.

2.5 Selection and Enucleation of Recipient Oocytes

The oocyte cytoplasm contains factors that reprogramme the donor cell genome after NT. Since these factors have not yet been molecularly identified, intact oocytes are still needed for NT, and phenotypic selection of oocytes with high reprogramming potential is currently not possible. Comparing oocytes of different developmental stages and maturation treatments for their utility during NT has defined a subpopulation of recipient oocytes that currently works best for somatic NT procedures. This subpopulation consists of mature nonactivated MII-arrested oocytes derived from developmentally competent follicles of slaughtered adult animals. Metaphase I (MI) oocytes, which are also high in M-Cdk activity, have proven equally suitable recipients as MII, at least for NT experiments in frogs. In pigs, however, MI oocytes result in lower *in vitro* development rates, suggesting that high M-Cdk is necessary, but not sufficient for nuclear reprogramming. MI and MII oocytes can be sourced from prepubertal or adult animals and both types have supported development of cloned embryos into offspring. The maturation from MI to MII oocytes can occur *in*

vivo or *in vitro* and both *in vivo* and *in vitro* matured oocytes have been successfully used for cloning. Further direct comparative studies are needed to fully evaluate the influence of oocyte source and maturation method on cloning efficiency. As outlined above, for somatic donor cells, preactivated MII oocytes result in poorer development than nonactivated oocytes, presumably because maintenance of an intact donor nuclear envelope in a low M-Cdk environment does not allow efficient chromatin remodeling to occur. However, low M-CdK oocytes are suitable for blastomere cloning where most donors are in S-phase. Aging of oocytes lowers M-Cdk level, which has been shown to be beneficial in blastomer cloning. Fertilized oocytes (zygotes) and early-cleavage-stage embryos (2-cell blastomeres) have also been successfully used for early mammalian cloning experiments with embryonic, but not somatic, donor cells.

Oocyte availability often fluctuates and might limit the optimal use of cloning facilities. Cryopreserved stored oocytes have been used successfully for somatic cell NT in bovine.

Prior to NT, the genetic material of the recipient cell has to be removed or destroyed. This process is known as *enucleation*, irrespective of whether the genetic material is surrounded by a nuclear envelope or not, and the resulting enucleated recipient is called *a cytoplast*. Efficient enucleation should completely inactivate the recipient genome without compromising viability and reprogramming potential of the cytoplast. In newts and in frogs of the genus *Rana*, enucleation is done by lifting the egg pronucleus and surrounding cytoplasm out off the egg with a needle (''Porter's technique,'' 1939). The strength and elasticity of the extracellular matrix surrounding *Xenopus* eggs prevents using this method in this frog species. Instead, short exposure (less than 1 min) of the egg to ultraviolet (UV) irradiation inactivates the egg pronucleus, apparently without otherwise damaging the egg. In mammals, UV irradiation for similar time intervals, alone or in combination with the bisbenzimide DNA stain Hoechst 33342, compromises both oocyte membrane and intracellular components and is therefore not used for enucleation. Instead, a capillary glass needle is usually used to gently aspirate the chromosomes and some surrounding cytoplasm (the so-called *karyoplast*) without penetrating the plasma membrane (Fig. 6). In young MII oocytes, the chromosomes are typically, but not always, located underneath the first polar body. However, in aging MII oocytes, for example, after prolonged *in vitro* maturation, the polar body gets frequently displaced from its original position, making enucleation more difficult. Therefore, enucleation solely relying on the polar body as an indirect morphological landmark is less accurate than directly visualizing the chromosomes. Visualization can be done either by various transmitted light contrast methods, such as differential interference contrast after Normarski (DIC), Hoffmann modulation contrast (HMC), or polarized light (Pol-Scope), in species with transparent cytoplasm (e.g. mouse and rat) or by epifluorescence microscopy after staining the DNA with fluorochromes in species with opaque cytoplasm (e.g. cattle, sheep, and pig). Enucleation accuracy with such methods is close to 100%. The short-term exposure to transmitted or fluorescent light has no obvious detrimental effect on cloned embryo viability and survival. A slightly more invasive method than using a glass needle for aspiration is to manually cut the whole oocyte in half and

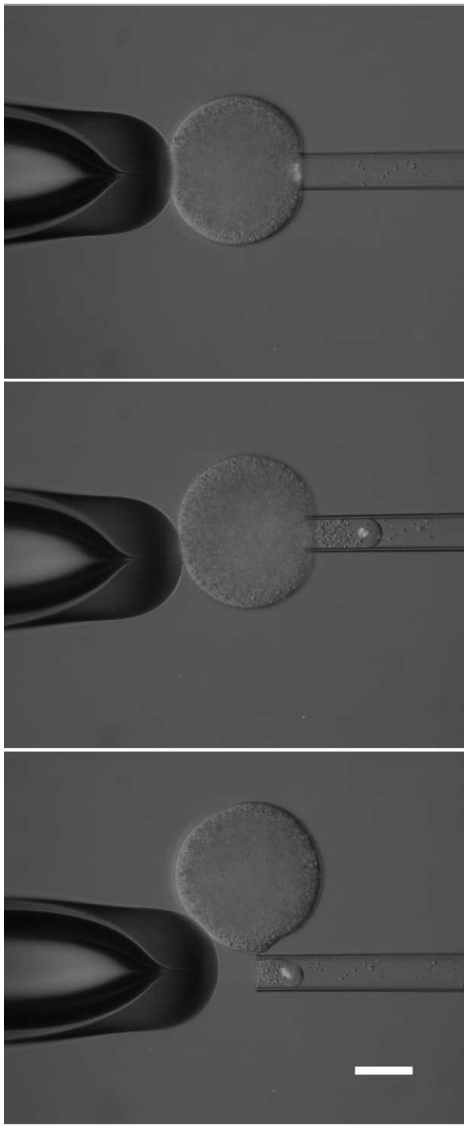

Fig. 6 Enucleation of bovine oocytes. DNA of the recipient egg is stained with a fluorescent dye (shown in blue) and mechanically removed with a fine glass needle. The plasma membrane is not penetrated during the procedure. Scale bar = 40 µm. (See color plate p. xxvii).

then UV-selecting and discarding those halves that contain the maternal chromosomes. Oocyte bisection does not use expensive micromanipulation equipment; however, it requires fusion of two half-cytoplasts in order to restore the original cytoplasmic volume, thereby wasting 50% of the original oocyte starting material. Furthermore, such cytoplasts contain two different genotypes of mitochondrial DNA, increasing the incidence of mitochondrial heteroplasmy.

An alternative method that avoids extensive micromanipulation or fluorescent light exposure is chemically assisted enucleation. This method has

been tried for more than a decade and aims to induce partial or full expulsion of the chromosomes in a pseudopolar body by using various combinations of microtubule-depolymerizing and oocyte-activating drugs. The main potential advantages are simplicity, ease of operation, and high throughput; however, so far it has only worked satisfactorily for mouse metaphase I oocytes. Irrespective of which enucleation method is employed, the quality and quantity of cytoplasmic components that are inevitably removed during the process may be critical. Depending on the method and skills of the operator, mechanical enucleation using a glass needle removes between 2 to 30% of oocytoplasm, containing not only the recipient DNA but also chromatin-associated proteins, the metaphase spindle complex, and its adjacent plasma membrane domain. The exact molecular composition of the karyoplast needs to be determined in order to better appreciate the potential developmental consequences of enucleation.

2.6 Nuclear Transfer Method

The step of introducing the donor cell DNA into the recipient cell is called *nuclear transfer* (NT), even though it is commonly not isolated nuclei that are transferred, but whole cells. The difference is probably not critical and both *bona fide* NT (by microinjection) and various whole-cell NT approaches (by fusion) have been successfully used.

2.6.1 Nuclear Injection

Intracellular injection of mechanically isolated nuclei was the first, and for many years the only, method of NT. It was part of the original amphibian cloning procedure by Briggs and King and was only adopted for mammalian NT in the 1990s, first in cattle and later in mice. For microinjection, the donor cell membrane is mechanically ruptured within the glass injection pipette and then injected within a few minutes of isolation. The amount of coinjected donor cytoplasmic components (cytoplasm, organelles) and culture medium is small compared to electrical fusion approaches. On the other hand, direct injection is technically more demanding and may require specialized equipment, such as a piezo-driven injection unit (a device that allows rapid movement over short distances), to minimize oocyte lysis during the procedure. Owing to these technical restrictions, NT of large donor cells (such as blastomeres, fibroblasts, or mitotically arrested donor cells) is typically done using fusion methods.

2.6.2 Fusion

Fusion methods are easier to master and by far the most widespread method of NT. Fusion was first achieved by exploiting the naturally fusiogenic properties of inactivated Sendai virus and later by using electrical pulses. In both cases, the plasma membranes of cytoplast and donor cell are brought in close proximity and fusion of the lipid bilayers is triggered either by catalytic viral fusion proteins or electrical pulses. In contrast to direct injection, during fusion, all cytoplasmic and plasma membrane contents of the donor cell, including organelles, centrosome, and cytosolic factors are introduced into the cytoplast. The consequences of this are not clear. Given that most oocytes are about 5- to 10-fold larger in diameter than the typical somatic donor, the donor contents get diluted by 1 to 2 orders of magnitude in the oocyte plasma

membrane and 2 to 3 orders of magnitude in the oocytoplasm, potentially minimizing their impact on subsequent development. Direct comparisons between piezo-actuated nuclear injection and electrical fusion in cattle found no significant differences in calving rates between the two methods.

Other variations of the injection/fusion methods have been explored, including injection of intact cells (rather than isolated nuclei) and fusion of transiently permeabilized cells containing artificially condensed chromatin; none of these approaches have resulted in significantly increased cloning efficiency.

2.7 Artificial Activation

Cloning subverts the sperm-mediated fertilization step that would normally lead to physiological activation of the oocyte. Since mammalian donor cells are unable to activate the recipient cytoplast, various artificial activation protocols have been employed that are meant to mimick the sperm-induced cellular events that typically occur during oocyte activation. These events include triggering of the inositol-1,4,5-trisphosphate signal transduction cascade that leads to characteristic transient intracellular calcium oscillations, initiation of the cortical granule reaction, degradation of M-Cdk, and formation of a new diploid embryo called a *zygote*.

There are a variety of agents that activate mammalian oocytes and the choice of which one to use for cloning has been largely empirical. Most current activation protocols work by sequentially administering an artificial stimulus (e.g. electric current, calcium ionophore, ethanol) followed by chemicals that are known to suppress M-Cdk reformation or activity (blockers of translation or broad-spectrum protein kinase-inhibitors, respectively). Comparative studies have so far not found any significant differences in cloning efficiency between different oocyte-activating agents. However, the origin, frequency, and amplitude of calcium oscillations are definitively altered in artificially activated eggs. Only a single calcium rise is induced by either an electric pulse or calcium ionophore, and, although this is sufficient to trigger cortical granule exocytosis and resumption of meiosis, repeated calcium oscillations may be more physiological and beneficial for later development. Likewise, downregulation of the inositol-1,4,5-trisphosphate receptor does not occur following *in vitro* oocyte activation. In addition, paternal messenger RNAs and early-sperm-derived transcripts might also be important in early embryonic development and are not delivered to the oocyte during NT. For these reasons, a zygote should theoretically make a much better recipient in terms of being properly fertilized; however, as noted under Sect. 2.4, it is not suitable for reprogramming somatic donors. One way around this dilemma is to use the zygote as a second recipient during serial NT. In this technique, the NT reconstruct is first allowed to form pronuclei and cleave before the pronucleus of each blastomere from the 2-cell NT embryo is microsurgically removed and transferred into an enucleated zygote during a second NT step. This way, the initial reprogramming occurs in the MII cytoplast, while the second NT step capitalizes on the better developmental potential of zygotic cytoplasm. The beneficial effect of serial NT has been demonstrated for cloning of mice and pigs. In summary, artificial activation and fertilization are functionally nonequivalent, and

one might expect different developmental consequences as a result of different activation protocols.

2.8 *In Vitro* Culture of Cloned Embryos

In particular in large mammals (e.g. cattle, horses, sheep), the transfer of early-cleavage-stage embryos into oviducts is technically more difficult and recipient animals are expensive. Therefore, cloned mammalian embryos are seldom transferred into recipient animals at the one-cell stage, but cultured *in vitro* for various periods of time, usually until reaching the blastocyst stage. In livestock, initial embryo culture in ligated sheep oviducts has now been virtually replaced by more defined culture methods using sequential media, where components change in accordance to the needs of the embryo, based on synthetic oviduct fluid (SOF). Studies in mice have shown that tailoring embryo culture medium to the requirements of the donor cell can also significantly improve development. Such refined *in vitro* culture systems allow selecting for NT reconstructs that are competent to complete preimplantation development and achieve blastocyst rates that are comparable to IVF embryos. However, this is unfortunately not a good predictor of later postimplantation survival after embryo transfer as most cloned embryos fail to develop into viable offspring.

2.9 Transfer of Cloned Embryos

In order to develop into viable cloned offspring, cloned embryos are transferred into appropriate surrogate mothers of the same or a closely related species. As noted under Sect. 2.8, most mammalian embryos are transferred into the uterus of recipient animals at the blastocyst stage, in particular, in large animals, where the high embryo wastage during preimplantation development would otherwise result in considerably increased cost for recipients. The number of embryos transferred varies between species. In ruminants, 1 to 4 embryos have been transferred in the past, but the trend is now toward single transfers. Since survival rates are comparable, this results in a 50 to 75% cost reduction. In pigs, pregnancy initiation requires a critical minimum signal from four embryos to the mother; consequently, the number of transferred embryo is much higher (>100). To minimize adverse *in vitro* conditions, some researchers have reduced the culture time to a minimum and transferred one-cell stage embryos into the surrogate oviduct. Goats and rabbits are similar to pigs in that respect, with 8 to 12 and 7 to 10 embryos at the 1-to-2-cell and 4-to-6-cell stage, respectively, transferred into oviducts. Transfer of early-cleavage-stage embryo circumvents potential *in vitro* culture artifacts. On the other hand, it does not allow using culture media tailored for the metabolic demands of the donor cell – a potential disadvantage, if the cloned embryos still exhibit somatic cell–like features.

Cryopreservation of cloned embryos would be beneficial to match the availability of transferable embryos and that of the recipients. Micromanipulated and *in vitro* cultured embryos are much more sensitive than flushed embryos; however, using advanced vitrification methods, cryopreservation of cloned bovine and sheep preimplantation-stage embryos has been successful. Pregnancy rates are reduced after such procedures, and further studies are needed prior to routine applications.

2.10 Pregnancy Monitoring and Progeny Production

After embryo transfer into appropriate foster mothers, pregnancy establishment and development throughout gestation are routinely monitored. A failure of the placenta to develop and function correctly is a common feature amongst somatic clones and has been documented for cattle, sheep, and mouse, but so far not for goat and pigs, indicating that species-specific problems with clones exist. Of particular concern are the losses in the second two-thirds of gestation; especially the occurrence of hydrops in cattle. Hydrops leads to acute excessive fluid accumulation in the allantoic (hydroalloantois), or rarely amniotic (hydroamnion), sac. It naturally occurs only in 0.02% of bovine pregnancies. Following artificial insemination or IVF, the incidence raises from 0.1% to up to 5%, respectively. In cloned cattle, however, up to 25% of pregnant cows at midgestation develop clinical hydrops. Cases are typically severe enough to kill the calves, and, in order to reduce the risk to the recipient cow, the standard practice is to terminate the pregnancy. Clones also often display parturition difficulties due to increased gestation period and birth weight and increased perinatal mortality due to respiratory distress is common in cattle, sheep, and mouse. To overcome problems owing to high birth weight, many clones are not delivered naturally, but by cesarean section.

2.11 Adult Clone Phenotypes and Transgenerational Effects

Somatic cell nuclear transfer is characterized by a series of developmental abnormalities collectively referred to as the *cloning-syndrome*. The cloning syndrome is defined as a predictable pattern of symptoms that occur together and characterize abnormalities caused by the cloning process. This encompasses higher rates of pregnancy loss, prolonged gestation, higher birth weight, higher rates of peri- and postnatal mortality, and specific adult phenotypes. Only about two-thirds of clones delivered at term survive at least until weaning. It has been claimed that at least these long-term survivors can be physiologically normal and apparently healthy, displaying normal behavior, growth rates, reproduction, and productivity. Equally, there are reports of various abnormal clone-associated phenotypes, including higher annual mortality rates in cattle, reduced maximal life span and obesity in mice, and compromised immune function in both species. The incidence of these anomalies varies according to the species, genotype, donor cell status, or specific aspects of the NT and culture protocols used, and it is not clear which of them could be eliminated by technical improvements.

Cloned offspring, produced by mating males and females cloned from the same cell line (namely, from male XY and phenotypically female XO ES cells), are normal and lack any obvious deleterious recessive genetic or epigenetic traits. This clearly implies that abnormal clone phenotypes are epigenetic in nature and can be corrected during gametogenesis. However, detailed molecular studies are required to exclude the possibility of subtle genetic alterations and to confirm whether all epigenetic modifications in clone-derived gametes are indeed restored to normal.

3
Applications of Nuclear Transfer in Different Species

Optimal conditions for NT vary among species. Comparative studies on reprogramming and organization of cellular elements and gene activation revealed factors potentially responsible for high variability in success rates among different species. Apart from species-specific aspects of nuclear reprogramming, in general good success is achieved in species where the level of general knowledge on embryology, especially on *in vitro* embryo production is advanced. The main goals and importance of basic research and practical applications varies among species as well. Nuclear transfer is succeeding in several new species every year, and the current status described in this section is likely to evolve rapidly.

3.1
Amphibians, Fish, and Birds

Experiments on *R. pipiens* and *X. laevis* frog species were the first to demonstrate the feasibility of cloning vertebrates, using different enucleation methods and various origin of nuclear material. Many of the mammalian experiments are simply verifying the existence of mechanisms first discovered in amphibians. However, there are several major differences in amphibian NT compared to that in mammals. The primary reason for developmental failure after NT may differ between amphibians and mammals. In Amphibia, the primary loss in somatic cell NT is during the first few cleavages as the majority of NT embryos with transplanted nuclei from differentiated or adult cells fail to divide, or undergo only a few irregular cleavages. In contrast, in mammals, the developmental loss tends to be greater after the initial cleavages. The explanation of this discrepancy might be found in the differences of the timing of the first cell cycle and the lack of imprinting in the amphibians.

In Amphibia, it is believed that nuclei from slow-dividing somatic cells cannot complete their chromosome replication in time (about 6 h needed) for the first cleavage of a recipient egg, which takes place according to the time schedule of the egg (at 1.5 h for the first cleavage in *Xenopus*). When the transplanted nuclei are starting mitosis with incompletely replicated chromosomes, chromosomal damage occurs and the defective embryos cannot survive. This might be the reason why failure in very early cleavages is the main source of losses in amphibians. When nuclei from differentiated or adult cells are used, a substantial proportion of NT embryos cleave abnormally and die as partial blastulae. However, when a second NT is performed (serial NT) with morphologically normal cells of partial blastulae into new enucleated eggs, many of the NT embryos develop relatively well in *Xenopus*, sometimes reaching the normal tadpole stage. These serial NT-derived tadpoles show the developmental potential of the original transplanted somatic cell nucleus, even though this potential was not realized by the first series of NT. The best explanation for this improvement in serial NT success might be due to the fact that in some cases the transplanted nucleus fails to complete chromosome segregation and the whole replicating transplanted nucleus moves into one of the first two daughter blastomeres. These blastomeres can complete the replication of its chromosomes before undergoing mitosis during the next cell cleavage and therefore the resulting

partial blastulae contain some normal blastomeres. Given a second chance during serial NT, these cells develop further normally. Besides serial NT, these normal looking cells from partial blastulae can be grafted to host embryos and demonstrate a wide range of developmental potential, including differentiation to normal muscle, notochord, epidermal, and other cells.

For reasons that are still not clear, nuclear transfer success declines rapidly with increasing donor age in *Rana,* and nuclear transplant development is much more successful in *Xenopus*. Despite decrease in success rates with differentiation, in some cases even nuclei of fully differentiated cells (intestinal epithelium of feeding larvae) were able to develop into normal, sexually mature males and females, thus establishing the principle that cell differentiation does not depend on losses or stable inactivation of genes. However, no such progeny have been obtained from donor cells of an adult frog, a major difference compared to mammals.

The connection between amphibian and mammalian experimental systems remains strong. Nuclei of differentiated adult cells of mice (thymocytes) and humans (white blood cells) can be to some extent reprogrammed by *Xenopus* oocytes, including the induction of pluripotency stem cell marker gene *Oct4* in the mammalian nuclei after injection into the oocyte nucleus. As amphibian oocytes contain molecules and conditions that can at least partially reprogram nuclei of adult mammalian cells, the large *Xenopus* oocytes, which have 4000 times the protein content of a mammalian egg and can be collected in big quantity (one female contains about 25 000 oocytes), provide a formidable tool for further research. Nuclear transfer has been achieved in other Amphibians, such as axolotl and *Pleurodeles*, as well.

Fish nuclear transfer has been achieved with transfer of embryonic cells into nonenucleated (generating triploid sterile progeny) or X-ray enucleated (generating cloned fertile progeny) unfertilized eggs in medaka (*Oryzias latipes*), and, to some extent, with embryonic and somatic cells in loach, cyprinidae, and, recently, in zebrafish, as well. The methods might open new possibilities for transgenic (TG) fish production and species preservation.

Attempts in birds for NT are intense, as it would present a potential method to produce TG chicken and other birds for medical and agricultural purposes, but the technical difficulties have so far prevented birth of cloned chicks.

3.2
Laboratory Animals: Mouse, Rat, and Rabbit

In mammals, there is a much longer time between the time of fertilization and the first cleavage division, therefore it is unlikely that incomplete chromosome replication is a problem like in Amphibia. However, mammals have imprinted genes not present in Amphibia, and their incomplete reprogramming can be a main reason for the high prevelance of later-stage losses, as discussed in details above. The presence of the placenta is another major difference, and in cloned mammals abnormal gene-expression patterns often reside prevalently in the placenta, rather than in the fetus itself. Placental cell lines often undergo DNA endoreplication or are multinucleated. Expression of placental genes in the adult could be deleterious, therefore they are strongly repressed in the genome. This repression is often not properly reversed during NT.

Other main differences of mammalian NT compared to Amphibia are due to the technical steps applied. In mammals, nuclear donors are often cultured cells, which raises the possibility of introducing noncontrolled epigenetic and genetic alterations. Mammalian NT enucleation removes maternal spindle proteins, which might be required to maintain ploidy through the initial cleavages. Failure to rupture the cell membrane of an injected donor cell might result in lack of cleavage, although recent studies have shown success with entire cells as well.

Mouse NT, despite many technical difficulties, is relatively well established in several laboratories around the world. A special aspect of mouse NT is the use of ES cell lines capable of generating germ line chimeras, which are not available in any other species. Several new technologies and molecular biological events are studied preferentially in mice, but the practical production of TG animals in this species is not likely to be dominated by the NT procedures in the near future, as the existing microinjection and ES cell technology–based methods work efficiently.

Rat NT is one of the biggest technological challenges, partially due to the high sensitivity of rat oocytes to spontaneous parthenogenetic activation. Recently, rat NT succeeded as well, using chemicals that block preactivation before NT. Use of TG rats in the pharmaceutical testing of new drugs might be one of the main activities in the future, and NT might represent a viable method to produce stable knockout and knockin animals in this important species.

Rabbit NT has been successful in producing progeny with fresh cumulus cells, but not with cultured cells. In this species, the first birth of progeny was partially due to a change in the ''asynchrony'' between the embryo recipient female's cycle and the NT-derived embryo age during embryo transfer, thus demonstrating the importance of species-specific technological adjustments. Rabbits are particularly important due to the possibility of using them as ''mammary gland bioreactors'' for secretion of TG proteins in the milk. Several TG human disease models could be developed in rabbit, which are not available in mouse, owing to anatomical and physiological differences (e.g. cystic fibrosis, atherosclerosis). Furthermore, placenta structure of the rabbit resembles that of the human, providing a chance for model studies on human reproduction.

3.3 Farm Animals: Sheep, Cattle, Goat, Pig, and Horses

Success rates of somatic cell NT are the highest in sheep and cattle, partially due to the high technological level of supporting embryo technologies.

Sheep was the first large animal species, where NT resulted in progeny from differentiated cells. Soon after, TG sheep carrying human blood factor genes have been generated via NT. Furthermore, the first gene-targeted animals other than mouse have been produced in this species. Sheep cloning efforts are continuing and are aimed at creating new TG animals for pharmaceutical protein production (in their milk or blood) or as models for human diseases (Fig. 7).

Cattle NT is the most efficient among all species studied and *in vitro* methods are used extensively. Recipient oocytes are usually collected from slaughterhouse ovaries and matured *in vitro*, thus reducing the expenses of the cloned embryo production. Embryos are cultured *in vitro* until blastocyst stage and then one or two embryos are transferred. In some cases,

Fig. 7 Lambs cloned by nuclear transfer with skin fibroblasts from a single founder individual of disease-resistant genotype. Producing identical copies of animals with such special genotypes is highly desirable for both basic research and commercial applications.

Fig. 8 Cloned bulls derived from adult skin fibroblasts of an elite crossbred steer. Clones from progeny-tested sires can transmit their elite genetics either through natural mating or increased semen production for artificial insemination. Cloning could be extremely useful in multiplying small numbers of genetically superior crossbred animals to maximize the benefits of both heterosis and greater uniformity within the clonal family.

around 25% of produced embryos go to term (Fig. 8). Animals have been produced from several cell types, including samples from steaks. Cryopreserved NT embryos have also been suitable for progeny production. There are potential applications of bovine NT in dairy, beef, and pharmaceutical industry. In dairy herds, cloned cows would greatly enhance progeny testing efficiency, and thus genetic progress. Also, rare or high-value animals, especially elite cows, can be reproduced this way. Even top genetic combinations achieved in F1 generation could be repeatable this way. In beef herds, cloned elite bulls or steers could be used instead of artificial insemination to distribute top genetics. Cloned bovine are allowed to enter the food chain in Japan, and are expected to be allowed in the US market in the near future. Furthermore, NT-produced cattle are tested for production of TG human proteins (including IgG antibodies) in their milk or blood.

Goat cloning has been successful, and herds of cloned TG goats have been established for human pharmaceutical protein production. There are also TG animals multiplied by NT, producing spider silk proteins, a source for a potentially high importance technical material in their milk. The use of *in vitro* matured oocytes has been successful in this species as well.

Porcine nuclear transfer progressed more slowly due to the difficulties with *in vitro* technologies and pregnancy establishment in this species. By now, the technology has been successful in many aspects, including production of progeny from slaughterhouse produced recipient oocytes and use of efficient activation methods and gene-targeted somatic cells. In order to establish pregnancies, often a very large number of embryos is transferred (over 100/recipient). The main focus of the porcine nuclear transfer was the production of TG animals suitable as

organ donors for humans (xenotransplantation). Despite the promising progress with the pig NT technology, many of the research projects have been aborted due to concerns of the presence of endogenous retroviruses in the porcine genome. Human disease models are also expected to be developed in this species, sometimes remarkably similar to humans in its physiology. In the long term, pig industry might profit from cloning top hogs, and distributing them to producers. A flattened pyramid in production systems and a greater flexibility of answering changing demands of the market could be achieved with NT. An important issue in these cases might be an increased demand for good management in order to avoid inbreeding due to the NT procedures.

In horses, numerous technological difficulties slowed down the first cloning attempts until recent success in Italy with adult somatic cells as nuclear donors. Interestingly, the embryo transfer recipient in that case was the nucleus donor as well, thus it gave birth to her own clone. Strict breeding regulations might reduce the practical applications in this species, especially in thoroughbreds. Furthermore, mule cloning has been successful, generating progeny from genetically nonfertile individuals in the United States. In the future, these animals might be used for mule racing competitions.

3.4 Endangered Species and Companion Animals

Endangered species preservation uses many reproductive techniques less expensive and much more efficient than present NT methods. However, in certain cases, NT offers advantages, such as creation of potential gene banks from any somatic tissues, including skin samples. Especially in field conditions, it would be relatively easy and noninvasive to obtain skin or hair samples, while gametes or embryos can be obtained only with much more difficulties. It would be especially beneficial in frog, fish, and bird species, where long-term preservation of female gametes and embryos has never been achieved.

In mammals, efforts to clone pandas, tigers, and other flagstaff species are gaining much attention. Saving the last remaining individual of an endangered bovine breed in New Zealand has been successful. Interspecies nuclear transfer would provide a major advantage by combining the availability of large number of bovine or other common species oocytes with that of somatic cells from a rare species. Experiments with bovine oocytes as recipients and donor cells from several species, including rats, sheep, pigs, monkeys, and humans resulted in further embryo development. However, so far only NT using donor cells and recipient oocytes from closely related species from the same genus (gaur or banteng and bovine; mouflon, argali (wild-sheep) and domestic sheep; African wildcat and domestic cat) resulted in pregnancies or progeny. Some of these animals died shortly after birth, potentially due to incompetence between the new nuclear material and the recipient oocyte mitochondria. A good demonstration of the potential of NT in species preservation is the case of a cloned African wildcat male, which was successful in breeding with wildcat females. Despite the male being heteroplasmic for wildcat and cat mitochondria, owing to the selective inheritance from only females the next

generation progeny contained only wildcat specific mitochondria.

Cloning efforts of extinct species, including Tasmanian tiger and mammoths have been started with much media attention, although owing to lack of good quality donor DNA and closely related recipient cytoplasts, the chances of success are very remote.

In companion animals, cat cloning has been successful. Commercial services for tissue collection, banking, and NT for recreating dead favorite pets are offered in several countries. Experimentation on creating TG nonallergenic cats via NT is also ongoing. In dog, no cloned progeny has been produced so far, despite intensive research efforts.

3.5 Humans and Nonhuman Primates

In humans, nuclear transfer has two potential applications. Both are using NT as starting steps, but the goals and final outcomes are profoundly different. Human ''reproductive cloning'' (i.e. production of a baby from a single individual's diploid cells) has been proposed and reported by some, but has never been confirmed scientifically. Adverse reaction of the public and the scientific community resulted in a strict ban of such attempts in most countries of the world.

The other approach is the ''therapeutic cloning'' (i.e. derivation of stem cells from embryos created with somatic cells of the patients), which would offer a chance to produce immunologically acceptable cells from and for patients. Therapeutic cloning is accepted and supported in many countries, although it is also often criticized and affected by the adverse reactions toward ''reproductive cloning.'' Success in producing cloned human embryos followed by isolation of embryonic stem cells has been reported from South Korea, although the characterization and therapeutic potential of these cells needs further verification. Recent attempts on transfer of human somatic cells into enucleated animal oocytes (bovine and rabbit) resulted in further embryonic development; however, isolation of stable ES cell lines from the ''hybrid'' human-rabbit embryos was not successful. Earlier experiments on introduction of mitochondrial DNA from chimpanzee, pygmy chimpanzee, and gorilla into mitochondrial DNA-less cells were capable of restoring oxidative phosphorylation, while mitochondrial DNA from orangutan, lemur, and other monkeys failed to do so, thus demonstrating the importance of genetic compatibility for nuclear–mitochondrial interactions and the potential difficulties of NT between distant species.

In nonhuman primates, nuclear transfer would be useful in producing identical animals for research purposes, thus reducing the number of individuals required to obtain reliable data on treatment effects. Furthermore, rare animals with heritable diseases (retinitis pigmentosa, congenital hypothyroidism) could be multiplied with NT and used for developing therapies. Considering the high value of oocyte donor females and limited resources in these species, cloning attempts are rather expensive and are progressing slowly. Despite success in producing *in vitro* NT blastocysts with embryonic blastomeres, ES cells, and somatic cells, so far only those from embryonic blastomeres resulted in progeny. There are reports on producing identical ''cloned'' twins with the embryo splitting method, which is very different from the NT techniques. Efforts continue

to produce cloned offspring from ES and somatic cells.

3.6 Ethical and Animal Welfare Aspects of Nuclear Transfer Research

Birth of ''Dolly,'' the first adult cell-derived sheep, initiated an intense debate on the potential of human cloning. The technical feasibility and potential impact of human reproductive cloning have often been misrepresented and exaggerated in the media and by some interest groups. From a technical point of view, the present state of the art in all species studied shows a low success rate and often serious health problems in the first generation of NT-derived animals. There is no scientific reason to believe that this would be different in humans, therefore, at present, there is no guarantee of producing only healthy babies by NT. Any human experimentation aimed to produce a progeny would be irresponsible and unethical at this stage. Despite this, several medical doctors and religious sects reported pregnancies and even birth of ''healthy cloned babies.'' None of these reports have been scientifically confirmed, and they are most probably manipulations of the truth rather than nuclear materials. The public and legislative reactions have been very intense and mostly uniform, and have resulted in a total ban of human reproductive cloning in most countries of the world.

On the other hand, human therapeutic cloning has divided society much more and become a very complex issue; beyond the scientific arguments, the legal and societal acceptance of the technology in various countries is strongly affected by differences in culture, religion, and political standing. The spectrum of opinions varies from total refusal of the method (for example, by several religious groups, together with other forms of research involving destruction of human preimplantation stage embryos) to the strong urging of speeding up further research (for example, from some patient's interest groups, hoping for new cell therapeutic treatments in the future). Evolution of the societal and ethical judgment of therapeutic cloning is very fast and strongly connected to that of human embryonic stem cell research and its progress toward potential applications. South Korean scientists reported success in producing such embryos, and license for such experiments has been given to a research team in the United Kingdom in 2004, in accordance with a parliamentary legislative decisions from 2001.

One of the main ethical problems is related to the use of human oocytes for the generation of a human preimplantation stage embryo and then its destruction in order to isolate the embryonic stem cells. Legislation varies in different countries on the use of oocytes and embryos for research purposes. Often, one of the main distinctions is whether the oocytes and embryos have been produced specifically for research purposes, or are surplus ones from fertility treatments donated for research. The ''Oviedo convention'' ratified by many European countries forbids the first version and also any financial or other compensations for the donors of the biological materials. Regulation on experiments using human cells transferred into animal oocytes is not clear in most countries, neither is the status of such embryos clear from a legal point of view. As it was described in the endangered species section, it is not proven yet, whether embryos from two remotely related species would be able to develop into progeny, therefore it is not

clear whether theoretically these embryos could become human beings or not.

Society can resolve the ethical issues through open discussion and consensus reaching. Scientifically, there is also hope for resolving the ethically sensitive issues. In the future, research efforts aimed for the understanding of the nuclear reprogramming process will hopefully result in ''oocyte-free'' systems, which would be able to reprogram somatic cells into a ''embryonic stem cell-like'' status, thus would provide cells for therapy without the sacrifice of any human oocytes or embryos. Another solution would be the generation of ES or other kind of stem cells (most probably by genetic engineering), which are immunologically tolerated by any of the recipient patients during therapy. Until that stage, however, further studies and debates on therapeutic cloning can be expected.

Animal welfare of the NT animals is a complex issue. Beyond the usual measures to assure the well-being of experimental animals, the low efficiency of NT due to losses during pregnancy and after birth represents a welfare challenge. Improving the efficiency by reducing such losses would be very important, and technological changes must be evaluated in the light of the health status of the fetuses, recipient females, and progeny. In case of serious abnormalities during pregnancy or after birth, long-term suffering must be avoided by terminating the pregnancy or by humanly killing the suffering animals. There is a general hope that the successful outcome of some of the NT projects ultimately would result in reduction of the number of experimental animals needed. Furthermore, welfare issues are only associated with the NT-produced founder generation as subsequent generations derived from naturally mating cloned animals seem to be free of epigenetic errors and appear healthy.

The public attitude toward acceptance of NT-derived farm animals in the food chain, or cloning and genetic modification of companion animals in order to reproduce lost ''friends'' or to obtain nonallergenic cats varies and is likely to result in public debates in the future. Improving the information level of the public must be taken seriously by researchers, as frequent misinformation by media has led to many misbeliefs. An example for misleading information is the cause for the death of ''Dolly,'' the cloned sheep who was put down due to an infectious pulmonary disease in 2003, not related to deadly NT side effects (only slight arthritis was detected postmortem), as often portrayed by the media.

4 Future Perspectives of Nuclear Transfer

Nuclear transfer is a fast developing technique, far from being optimized. Evolution in efficiency and applicability in new species is expected. However, it is not clear how much of technical development can be achieved by simply improving the present protocols. Revolutionary changes in our understanding of the reprogramming of the nuclear material, organization of chromatin, and epigenetic changes might be needed to have a proper control of the procedures, thus avoiding epigenetic aberrations in progeny.

Basic research in nuclear reprogramming will continue, especially due to connections to the ES research field. Practical application of NT in the near future is expected in the agriculture for enhanced food production and propagation of superior breeding stock; in medicine by using

animals as novel disease models, bioreactors, and organ donors produced by the combination of transgenesis/homologous recombination in somatic cell lines and NT; and in therapeutic cloning of human embryos. Methods with much improved efficiency would provide a good tool for endangered species preservation efforts as well. In case of industrial utilization, the importance of avoiding inbreeding with advanced breeding management will increase.

5 Concluding Remarks

The NT field is still in its infancy, concerning the complexity of the procedures involved and its low efficiency. Its initial effect by breaking the dogma of ''irreversible cell determination'' was very important, and affected the further development of stem cell and other research fields. After the production of Dolly, many scientists working on gene expression and chromatin structure got interested in using nuclear transfer as a research tool in studying epigenetic reprogramming, and now the underlying molecular mechanisms and contributing factors are getting revealed in several animal models.

The present fascination of the public shows how much the possibility of replicating existing individuals captured the imagination of many people; however, the true importance of NT will be decided only as time goes by, and by the continuing efforts of the scientific community.

Acknowledgments

The authors would like to thank Dr. Szilard Bodo for drawing Fig. 2 and Jacqui Forsyth for providing photographs of the cloned animals. A. Dinnyes has been supported by the Wellcome Trust, UK (International Senior Research Fellowship in Biomedical Science in Central Europe No. 070246), an EU FP6 Marie Curie Excellence Grant (FP6-509582), by the Hungarian National Office of Research and Technology (FEFA KMUFA BIO-00017/2002) and OTKA No. T046171 grants.

Keywords

Markov Process
A mathematical model of infrequent changes of (discrete) states over time, in which future events occur by chance and depend only on the current state, and not on the history of how that state was reached. In molecular phylogenetics, the states of the process are the possible nucleotides or amino acids present at a given time and position in a sequence and state changes represent mutations in sequences.

Maximum Likelihood
The likelihood of a hypothesis is equal to the probability of observing the data if that hypothesis were correct. The statistical method of maximum likelihood chooses amongst hypotheses by selecting the one which maximizes the likelihood; that is, which renders the data the most plausible.

Phylogenetic Inferences
The statistical methodology based on the study of phylogenies and processes of evolution by the analysis of DNA or amino acid sequence data.

Phylogenetic Tree
The hierarchical relationships among organisms arising through evolution. The tree comprises a set of nodes linked together by branches. Terminal nodes typically represent known sequences from extant organisms. Internal nodes represent ancestral divergences into two (or more) genetically isolated groups; each internal node is attached to one branch representing evolution from its ancestor, and two (or more) branches representing its descendants. The lengths of the branches in the tree can represent the evolutionary distances that separate the nodes; the tree topology is the information on the order of relationships, without consideration of the branch lengths.

Bioinformatics is the application of computer technology to the management and use of molecular biology and genetic information. It is based on computer science and statistics; the current focus is on probabilistic models to analyze biological sequences at the genome level and other ''omics'' levels (e.g. transcriptomics and proteomics data). The major challenge in bioinformatics is the accurate prediction and modelling of the genomewide RNA:DNA, RNA:RNA, protein:DNA, protein:RNA, and protein:protein interaction patterns in the entire range of cellular and extracellular environments. This achievement would lead to the solution of the principles of genome-structure organization, the identification of the transcription initiation and termination and the RNA splicing pattern of any primary transcript in any tissue and the precise prediction of the folding pathway of any protein, the formation of quaternary and quinary (intermolecular) structures, and the design of effective drugs. Here, we summarize the state of the art and the potential of

sequence analysis. Since a single review cannot describe the ever-broadening subject that is genome analysis, we proceed by discussing methods for genome composition analysis, gene- and transcription-site identification, and analysis of repeats, and conclude with speculation on the future course of bioinformatics analyses.

1 Principles of Genome Sequence Analysis

Genome studies have become central to a wide range of biological areas. The term *genome* derives from Gene + Ome. A gene is an ordered sequence of nucleotides located in a particular position on a particular chromosome that encodes specific functional products (i.e. protein or RNA molecules). It contains upstream regulatory regions. The suffix ''Ome'' is, according to Merriam-Webster dictionary, from the Latin word for ''mass''. The genome, therefore, represents the whole genetic information content of an organism. Genome analysis involves the description of the general rules that allow an organism to utilize and combine the different types of information present in the genomic sequence, within its physiological and environmental contexts. There is no unique criterion for describing the genome of even the simplest organism. The situation can be well represented by the analogy from engineering drafting where blueprints of some complicated machinery are usually replaced with an exploded view of the same, with each component shown from many different angles or in holographic view. Similarly, location and abundance of coding regions, transcription signals, and repeats, are usually represented in the form of several color-coded wheels. Values that are more than plus or minus three standard deviations from average are shown as very dark lines in the diagram. Genome sequences have been investigated on the basis of several characteristics, for example, linguistics, percentage of shared homologous genes, and patterns associated with physicochemical properties of sequences, such as base stacking energy, propeller twist and curvature, and genomic features such as ancient repeats, gene family composition, and metabolic pathways. An important first step is to identify large regions with remarkably different sequence composition. These may result from lateral gene transfer in bacteria or from the existence of isochores (defined in Sect. 2) in higher vertebrate genomes. This analysis is generally termed *genome segmentation*.

2 Genome Segmentation Analysis

Genome segmentation methods are usually based on the assessment of the statistical significance of over- and underrepresented oligomers in complete genomes. The analysis of the bias of oligomers requires a model of how sequences are generated and the statistical distribution of the oligomer. The simplest composition analysis is the counting of guanines and cytosines. The G + C content is an interesting statistical property of a genome since there are large differences both within and between genomes. In bacteria, genomic islands with different G + C content with

respect to the neighboring regions are generally the result of lateral gene transfer and recombination events. In pathogenic strains, some of the G + C islands carry virulence genes that code for toxins, adhesins, invasins, or other virulence factors.

Vertebrate genomes are made up of long DNA segments, the isochores, which are homogeneous in GC content and differ in gene content. For example, the human genome can be subdivided into five families, L1, L2, H1, H2, and H3, which are characterized by increasing GC levels and gene concentrations; the two GC-poor families (L1 and L2) represent 30 and 33% of the genome, respectively, and three GC-rich families (H1, H2, and H3) represent 24, 7.5, and 4 to 5% of the genome, respectively. Gene concentration reaches up to a 20-fold higher level in H3 than in L1 isochores. The isochore organization of the avian genome contains an additional GC-richest H4 isochore family. It is known that isochores are mainly present in genomes of warm-blooded vertebrates, while only very few cold-blooded vertebrates have isochore-like genomes Since a 10 °C increase in *in vitro* temperature corresponds to a 5.7-fold increase in the rate of cytosine deamination, Fryxell and Zuckerkandl proposed that the deamination of methyl-cytosine and cytosine might be the cause of GC isochores.

In order to detect GC-patterns, sequences are usually coded as C, G = 1; A, T = −1. A G + C profile is analyzed using a sliding window of fixed size, usually 10 to 50 kb, and by computing the chi-square statistics of the G + C content of each window with respect to the average value of the whole genome. The average difference in G + C content between two adjacent windows gives an estimate of the composition's heterogeneity. The localization accuracy of this method is of the order of the length of the window: if the window is small, its G + C content is subject to strong fluctuations, whereas if the window is large, it may conceal the heterogeneity.

Nekrutenko and Li have developed a compositional heterogeneity index, H_{gc}, to quantify and compare the compositional differences within and between genome sequences. The authors considered a sequence that can be divided into n windows of length L and calculated the genomic average $GC\%$, GC_{av}, and the GC content of each window, (e.g. GC_1, $GC_2, \ldots, GC_n$). Then, they computed the average GC-content difference between two adjacent windows, as given in Eq. (1).

$$H_{gc} = \frac{\frac{1}{n}\sum_{i=2}^{n} |GC_i - GC_{i-1}|}{\sqrt{\frac{GC_{av}(1 - GC_{av})}{L}}} \qquad (1)$$

where the term at the denominator represents the standard error, s.e.; the s.e. reaches the maximum value at $GC_{av} = 0.5$. Note that, if the window is small, its GC content is subject to strong fluctuations, whereas if the window is large, it may conceal heterogeneity.

An oligomer appears with an unexpected frequency in a sequence if the number of its occurrences is significantly different from an estimator of the expected count under the considered model. Karlin and coworkers have shown that the relative frequencies of dinucleotides from DNA segments within a genome are more similar than sequences from different organisms and that related organisms have similar dinucleotide patterns. Local analysis of dinucleotide relative abundances has been used to detect gene-transfer events. A common assessment of dinucleotide bias

is through the odds ratio $\rho_{xy} = f_{xy}/f_x f_y$, where f_x denotes the frequency of the nucleotide X and f_{xy} is the frequency of the dinucleotide xy. In order to accommodate double-stranded DNA, the sequence is concatenated with its inverted complementary sequence. A measure of difference between two genome sequences A and B (from different organisms or from different regions of the same genome) is the absolute difference of the dinucleotide relative abundance, which is calculated as given in Eq. (2)

$$\delta(A, B) = \frac{1}{16} \sum_{xy} |\rho_{xy}(A) - \rho_{xy}(B)| \quad (2)$$

where the sum extends over all dinucleotides xy. Dinucleotide-odds ratio values reflect the chemistry of dinucleotide stacking energies and the species-specific properties of DNA modification, replication, and repair mechanisms. Because of the hydrophobic forces, the stacking energy of the base pairs on top of one another is the most important property contributing to DNA-helix stability. Trinucleotides are correlated to dinucleotide abundances and, in order to factor out all the lower-order biases, the odd ratio is computed, as given in Eq. (3)

$$\rho = \frac{f_{xyz}\, f_x\, f_y\, f_z}{f_{xy}\, f_{yz}\, f_{xnz}} \quad (3)$$

where f_{xyz} is the frequency of the trinucleotide xyz and n is A,C,T, or G. Trinucleotide frequencies also reflect the codon-usage bias. The codon-usage bias can be used to predict gene-expression levels in prokaryotic and low eukaryotic genomes: genes that deviate strongly in codon usage from the average gene but that are sufficiently similar to ribosomal protein genes and to translation and transcription processing factors. Let suppose that "g_1" is a gene with average codon frequencies, $a(x, y, z)$, for the codon triplets (x, y, z) normalized so that $\Sigma_{(xyz)=a} g_1(x, y, z) = 1$, where the sum extends over all codons (x, y, z) translated to amino acid a; the codon-usage bias of the gene "g_2" relative to the gene "g_1" is calculated by the formula given in Eq. (4).

$$C\left(\frac{g_2}{g_1}\right) = \sum_a p_a(g_1) \left[\sum_{((x,y,z)=a)} |g_2(x, y, z) - g_1(x, y, z)| \right] \quad (4)$$

where $p_a(g_1)$ are the average amino acid frequencies of the gene g_1.

The standard methodology for longer words uses Markov chains to obtain a theoretical expectation for the count of an oligomer. The order k of the Markov chain model means that the probability that a base occurs at a given position in the sequence depends on the k previous bases. The choice of the order of the Markov model depends on sequence length because of the data requirements in estimation. There are two kinds of statistics to compare the theoretical expectation with the real observed count. For common oligomers, a Gaussian approximation is appropriate and the statistic is simply the z-score. For rare oligomers, a compound Poisson approximation is generally used. More specialized methods, which are used in gene prediction, implement hidden Markov models (HMM).

A discrete Markov process is a mathematical model of infrequent changes of discrete states over time, where future events occur by chance and depend only on the current state, and not on the history of how the state was reached. A hidden Markov model is a finite sequence of states;

the Markov property assures that the next state to occupy depends only on the current state. Each state is associated with a probability distribution and transitions among the states are governed by a set of probabilities called *transition probabilities*. In a particular state, an outcome or observation can be generated according to the associated probability distribution. It is only the outcome, not the state, that is visible to an external observer, and therefore, states are ''hidden'' to the outside; hence the name hidden Markov Model. The states might correspond to columns of a DNA multiple alignment or to positions in the three-dimensional structure of a protein. HMM methods have a very rich theoretical structure and use simple modular objects that can be added in various architectures to describe complex models. Churchill proposed an early HMM for genome segmentation. The model consists of two (hidden) states (AT-rich and GC-rich regions), the transition probabilities between these states and the probability distributions of the four bases for each state. Nicolas and collaborators have proposed a new statistical segmentation method based on a hidden Markov model and have estimated parameters using maximum likelihood. Their model has several hidden states, and it enables different compositional classes to be separated, for example, noncoding RNAs, coding regions for each DNA strand (+,−), highly expressed coding regions, genes coding for hydrophobic proteins, and intergenic regions. Their approach is not based on sliding windows, and it enables different genome compositional classes to be separated without prior knowledge of their content, size, and localization.

An effective method for detecting specialized islands is based on wavelet analysis, which is similar to Fourier analysis. In short, a wavelet is an oscillation that decays quickly. A Fourier transform decomposes a function into a sum of sine and cosine functions with different frequencies. The result of a Fourier transform is a series of amplitudes of sines and cosines that sum up to the original function. Instead, wavelet methods use functions that are related to fractals in that the same shapes repeat at different orders of magnitude. The basic idea of wavelets is to decompose a signal, for example, a G + C profile, into several groups of coefficients, each group containing information about features of the G + C profile at a certain scale of sequence length. Coefficients at coarse scales capture gross and global features, for example, clusters of genes or single genes with different G + C content. Coefficients at fine scales contain the local details (few nucleotides) of the profile. Therefore, the original plot can be replaced by a more regular one generated using the coefficients at coarse scales.

3 Detecting Genes

The most important step in the analysis of a new genome is the identification of all its genes. It is important to understand the difference between prokaryotic and eukaryotic genes. In both cases, it is a unit of heredity; however, in eukaryotes this unit may include both the protein-coding region and RNA-coding region of a DNA sequence. In prokaryotes, a gene refers only to the protein-coding region because multiple genes may be expressed from a single RNA molecule (an operon). In some cases, a dozen human genes can span the same length of an entire bacterial chromosome. There are approximately 30 000 genes in the human genome, but it

is important to realize that there may be as many as 300 000 gene products. These are the result of alternative splicing and posttranslational modification.

The standard methodology for gene identification is to find a similar sequence from another organism. This can be done using the BLAST and FASTA families of programs to search all the entries in sequence databases. Since prokaryotic genomes tend to be gene-rich with frequent overlaps, an open problem is the improvement of the accuracy of gene start and termination prediction. ''Glimmer'' and the ''GeneMark'' family of programs are the most widely used tools for microbial gene prediction. Structural RNA genes can be detected using QRNA. All these programs are based on HMMs.

Once a putative gene has been identified, its function can be investigated using the COG database, which contains clusters of orthologous groups of proteins, or a pathway database, for example, Ecocyc, which describes biochemical pathways, reactions, and enzymes in *Escherichia coli*. Additional functional information is given by the analysis of cotranscribed genes, that is, genes organized into an operon structure. Although operons can be located through the analysis of their boundaries, that is, promoters on the 5′ end, and terminators on the 3′ end, such approaches can only be effective for organisms whose promoters and terminators are well known. An alternative method finds gene clusters where gene order and orientation is conserved in two or more genomes and estimates the likelihood that such conserved gene sets form operons. The sensitivity of this method is 30 to 50% for the *E. coli* genome. Note that, although positive selection for operons would result in similarly ordered sets of genes across phylogenetically distant genomes, the conservation of gene order between evolutionarily similar organisms may simply reflect the common ancestry of the species.

3.1 Analysis of Duplicated Genes

Genes exist predominantly as families with related structures and functions. In particular, eukaryotic genomes contain a large number of duplicated fragments. There are different extents of duplication: a small part of a gene, a module, an exon, a coding region, a full gene, a cluster, part of a chromosome, or a full chromosome. Whole genome duplications are widely believed to have played an important role in the evolution of the yeast, plant, and vertebrate genomes. The human genome contains roughly the same number of gene families as insects and nematodes, although we have more abundant gene variety in each family. The probability of gene preservation increases with the number of independent subfunctions in the regulatory regions (transcription sites) and in the coding regions (alternative splicing of exons) because of the greater number of ways in which gene duplicates can evolve. The recombination, loss, acquisition, shuffling, and duplication of regulatory sites and exons will increase rather than decrease the probability of duplicate gene fixation because each gene can now perform a function the other gene cannot, for example, the two genes being expressed in different tissues or developmental stages. The probability of fixation by differential subfunctionalization approaches zero in large populations because the long time to fixation magnifies the chances that secondary mutations will completely incapacitate one copy before joint preservation is complete. Therefore, it is more important in high eukaryotes than in bacteria

and low eukaryotes where neofunctionalisation, that is, that completely new genes arise, is a more frequent event.

3.2 Phylogenetic Methods for Orthologous Genes

Phylogenetic methodology allows one to recognize and exploit the statistical dependencies among duplicated genes. For example, there are cases in which gene functions are inferred from pairwise sequence similarities to genes whose functions have themselves been inferred from pairwise sequence similarities. Since paralogous genes (those believed to have arisen by gene duplication within a species) may not have the same function, the phylogenetic relationships among sequences allows each species to contribute its own quantity to all estimates. The most statistically robust approach is to consider the phylogenetic inference problem in a likelihood framework and to use accurate models of evolution. Maximum likelihood estimation chooses the hypothesis that maximizes the likelihood of the data, that is, which renders the data the most plausible. In phylogeny, the model of evolution relates the hypotheses, that is, the tree topologies, to the data, that is the sequences. The maximum likelihood method allows one to estimate evolutionary parameters, such as heterogeneity of rates of evolution among sites and among lineages, transition/transversion and nonsynonymous (amino acid changing; d_N)/synonymous (silent; d_S) substitutions ratios; therefore, important biological questions can be addressed and tested. A great attraction of the likelihood approach is the ability to perform robust statistical hypothesis. Therefore, when more than two genome sequences are available, it is better to use phylogenetic methods than simple sequence pairwise comparisons and it is also better to use maximum likelihood than other methods. Phylogenetic methods also make appropriate corrections for multiple hits. In pairwise comparisons of sequences, the multiple-hit corrections differ for each pair because the evolutionary separation of two human sequences is not the same as the evolutionary separation of human and mouse or mouse and rat. Moreover, contiguous regions might have different evolutionary separations.

Gu has developed a quantitative measure for testing the function divergence within a gene family. The method is based on measuring the decrease in mutation-rate correlation between gene clusters of a gene family; the HMM procedure allows one to identify the amino acid residues responsible for the functional divergence.

Tandemly duplicated genes are known to be subject to gene-conversion events that homogenize their sequences. There are several methods for testing gene conversion among duplicated genes and repeats. Most of these methods are derived from the test proposed by Sawyer. This test allows one to detect identical segments of DNA between clustered genes that may indicate gene-conversion events. Sawyer's gene-conversion test, when applied to pairs of sequences, measures the sum of the squared total lengths (SSL) of these fragments. If gene conversion has been operating, fragment lengths would be more varied and SSL would be larger than if variant sites were distributed at random along the sequence. Therefore, the same number of variant sites is then randomly permuted along the sequence many times and the SSL for each replication calculated and compared to the observed value.

4 Detecting Regulatory Regions

Even though every cell in an organism contains the same genetic material, each cell does not express the same set of genes. Therefore, one of the major problems facing genomic research today is to determine which genes are differentially expressed and under what conditions and how the expression of those genes is regulated. The first step in determining differential gene expression is the binding of sequence-specific DNA-binding proteins (i.e. transcription factors) to regulatory regions of the genes, that is, transcription factor binding sites (TFBSs). Therefore, identification of the regulatory elements is necessary for understanding mechanisms of cellular processes. A significant number of prokaryotic genes and DNA-binding sites are involved in regulatory responses to factors such as growth arrest, cell density, nutrient starvation, and stress. These responses may form part of a complex regulatory network designed to match cellular physiology with optimal growth and/or survival. Regulatory networks are also important in switching on virulence genes in human, animal, and plant pathogens. In eukaryotes, the regulation of gene expression is highly complex and often occurs through the coordinated action of multiple transcription factors. This combinatorial regulation has several advantages; it controls gene expression in response to a variety of signals from the environment and allows the use of a limited number of transcription factors to create many combinations of regulators. DNA-binding sites are shorter than genes and lack the sharp delimitations of start and termination signals. Genes coding for DNA-binding proteins are usually less conserved than genes coding for structural proteins. Moreover, regulatory proteins work in modules. Rajewsky and collaborators have demonstrated an inverse correlation between the rate of evolution of transcription factors and the number of genes that they regulate. Therefore, it may be easier to dissect a large gene network than a small one.

Information-theory-based methods have been successful in identifying bacterial regulatory sites. It is known that specific hydrogen bonds and van der Waals interactions allow a protein to discriminate, that is, to extract a certain amount of information from a DNA-binding site. From information theory, we know that one bit is the amount of information required to distinguish between two equally likely choices: if a protein picks one of the four bases, then it makes a two-bit choice, that is, the first choice is between purine and pyrimidine. Several authors have proposed a likelihood quantity to estimate the amount of information in multiple aligned sequences containing a binding site; they also derived an approximation for *p*-values and variance. Theory predicts that, because of mutations, the information content at a binding site is kept from being larger than is needed for the regulatory function and that the sequence pattern of a binding site is related to the number of genomewide occurrences and to the size of the genome. These methods have the problem of many false positives and an important limitation: they assume that each site interacts with a single protein independently. Additional information on regulatory sites may come from structural studies, for example, bacterial promoters have been found to be curved and rigid.

Although there is now a detailed understanding of regulatory mechanisms in unicellular organisms, such as bacteria and budding and fission yeast, the

extension of such results to multicellular organisms and, in particular, to the human genome presents considerable difficulties. In single-celled organisms, most regulatory elements are located within 200 to 500 bp of the 5′ end of open reading frames (ORFs). In multicellular organisms, however, regulatory elements may be found upstream or downstream of the gene, as well as in introns, and may be spread over tens or even hundreds of kilobases. Experimental evidence suggests that regulatory elements are more probable within a few thousand base pairs 5′ of the transcription start site, but current algorithms are able to locate only some of these regions.

The challenge is to allow biologists to automatically (1) retrieve genes and intergenic regions; (2) identify putative regulatory regions; (3) score sequences for known TFBSs; (4) identify candidate motifs for unknown binding sites; and (5) detect those statistically overrepresented sites that are characteristic for a gene set. In this context, the difficulty for bioinformatics is twofold. First, the approximate localization of regulatory sequences in large anonymous DNA sequences is required. Once those regions are located, the second task is the identification of individual transcriptional control elements and the correlation of a subset of such elements with transcriptional functions. The sequence motifs of individual cis-elements are usually too short and degenerate for confident detection. In most cases, the requirements for organization of cis-elements within these clusters are poorly understood.

How many sites do we expect to find in a genome? Cawley et al. have mapped the binding sites *in vivo* for three DNA-binding transcription factors, Sp1, cMyc, and p53, in a microarray incorporating sequences of human chromosomes 21 and 22. This mapping reveals an unexpectedly large number of TFBS, with a minimal estimate of 12 000 for Sp1, 25 000 for cMyc, and 1600 for p53 when extrapolated to the full genome. Only 22% of these TFBS regions are located at the 5′ termini of protein-coding genes, while 36% lie within or immediately 3′ to well-characterized genes and are significantly correlated with noncoding RNAs. Most methods for identifying regulatory sites rely upon the assumption that the nucleotides of binding sites exert independent effects on binding affinity. Bulyk et al. determined the effects of many possible sequence variations in binding affinities of mutants versus wild-type transcription factor bound to microarrays containing all possible central 3-bp triplet-binding sites. They found that the nucleotides of TFBSs cannot be treated independently. In higher organisms, it is more likely that multiple transcription factors bind to the same transcription control region, and to understand the regulatory content of eukaryotic genomes, it is necessary to consider the co-occurrence and spatial relationships of individual binding sites. Several works suggest that positional information, especially the relative spacing between transcription-factor binding sites, may represent a common organizing principle of transcription control regions. Chiang et al. used the genome sequences of four yeast species of the genus *Saccharomyces* to identify sequences potentially involved in multifactorial control of gene expression. They found 989 pairs of hexameric sequences that are jointly conserved in transcription regulatory regions and that also exhibited nonrandom relative spacing. The incorporation of word pairs to define sequence features yields more specific predictions of average expression profiles and more informative regression models

for genome-wide expression data than on considering sequence conservation alone. King et al. introduced a nonparametric representation of TFBSs that can model arbitrary dependencies between positions. As two parameters are varied, this representation smoothly interpolates between the empirical distribution of binding sites and the standard position-specific scoring matrix (PSSM).

TFBSs detection involves the search of DNA patterns that are overrepresented in the upstream region of a set of coregulated genes. Several computational algorithms have been developed to this end. These methods fall into three broad classes:

1. The word-enumeration approach compares the frequency counts of substrings in the upstream region to some reference set.
2. The probability-based models update a position-specific probability matrix, using local multiple alignment searches. In this approach, the model parameters are estimated using Expectation-maximization (EM) or Gibbs sampling methods.
3. Methods using microarray data.

The major limitation of type-1 methods is that it represents cis-elements using degenerate consensus sequences rather than the more general position specific scoring matrices. An undesirable feature of many methods is the use of arbitrary threshold parameters, such as a window size within which the cis-elements must occur. Then, the choice of a DNA background model that adequately reflects the properties of natural DNA is more problematic to construct. There are usually three techniques: an independent mononucleotide model estimated from the query sequence, a higher-order Markov model estimated from genomic DNA, and a locally varying mononucleotide model estimated from a sliding window within the query sequence.

Djordjevic and collaborators classified potential binding sites by means of the estimate of sequence-specific binding energy of a given transcription factor. The method also estimates the chemical potential of the factor that defines the threshold of binding. This results in a significant improvement in the number of expected false positives, particularly in the ubiquitous case of low-specificity factors.

Comparative genomics seems more promising than single species analysis. In particular, owing to the high similarity of both biology and sequence between human and mouse, the mouse genome is receiving considerable attention as a tool for cross-species comparisons. This strong similarity, however, has raised doubts regarding the general usefulness of human–mouse sequence comparison for distinguishing functionally conserved features against a background of recently evolved sequence.

Loots et al. have developed a computational tool, rVista, that combines clustering of predicted TFBSs and the analysis of interspecies sequence conservation to maximize the identification of functional sites. They analyzed the distribution of several TFBSs across 1 Mb of the well-annotated cytokine gene cluster (Hs5q31; Mm11), focusing on the distribution of all binding sites specific for the transcription factors AP-1, NFAT, and GATA-3. The exploitation of the orthologous human–mouse dataset resulted in the elimination of >95% of the approximately 58 000 binding sites predicted on analysis of the human sequence alone, whereas it identified 88% of the experimentally verified binding sites in this region.

Although comparative genomics of regions (e.g. phylogenetic footprinting)

across different species is a very promising approach, it has been unclear as to which species are most useful and how many genomes are sufficient for comparison. There is the belief that the comparison of just three well-chosen species that have similar physiology, genome size, and whose phylogenetic distances are neither too small nor too large, may allow to correctly identify most of TFBSs. Margulies et al. have identified sequences that are conserved across several multiple species, ''Multispecies Conserved Sequences'', and have found that approximately 70% bases reside within regions. They used the Bayes block aligner, which focuses on aligning highly conserved, ungapped blocks in which regulatory elements are most likely to reside. The alignment algorithm first produces data represented by a two-dimensional histogram reporting the probability that each pair of nucleotides from two subject sequences are located within a conserved block. The recursive sampling algorithm yields a representative sample of alignments that can be used to calculate the probability that any given base in the first sequence aligns with a specific base in the second sequence. To bias the output towards alignments with short blocks of high similarity, they used the PAM1 similarity matrix, that is, a substitution matrix based on the assumption of only one accepted mutation per 100 bp. In this matrix, the probability of a transition is three times that of a transversion.

Several methods for searching for specific regulatory sites using Markov and hidden Markov models, Bayesian clustering, and Machine learning have been proposed. Qin et al. have developed a Gibbs sampling-based Bayesian motif clustering (BMC) algorithm that show fewer errors than hierarchical and K-means clustering methods.

It is important to mention another important component of the identification of TFBSs: databases of TFBSs and TFs. TRANSFAC is a database about eukaryotic transcription regulating DNA sequence elements and the transcription factors binding to and acting through them. Database of transcriptional start sites (DBTSS) was originally constructed on the basis of a collection of experimentally determined TFBSs of human genes and now covers several species. The positions of single nucleotide polymorphisms (SNPs) in dbSNP were displayed on the upstream regions of contained human genes. The CORG – ''Comparative regulatory genomics'' – database contains conserved blocks from the upstream regions of orthologous genes. These blocks were computed on the basis of statistically significant local suboptimal alignments of 15 kb regions upstream of the translation start sites of a large number of pairs, 10 793 at April 2004, of orthologous genes. The resulting conserved blocks were annotated with expressed sequence tags (ESTs) that are good indicators for putative exons.

The use of both sequence and gene-expression information is producing important results. Bussemaker et al. have considered both yeast sequences and expression data and have outputs of statistically significant motifs: the regions upstream of genes contribute additively to the log-expression level of a gene. Recently, Conlon et al. have proposed a very interesting approach. They have first identified a number of sequence patterns upstream the yeast genes using Mdscan and have then tested for candidate transcription sites. Their algorithm is based on fitting a linear regression with gene expression as response and a score based on transcription-site candidates as covariates: $Y_g = \alpha + \beta_m S_{mg+} \varepsilon_g$, where Y_g is the

$\log_2$ expression value of the gene g, S_{mg} measures how well the upstream sequence of a gene g matches a motif m, in terms of both degree matching and number of sites, and ε_g is the gene-specific error term. The baseline expression α and the regression coefficient β_m are estimated from the data. Then, they performed stepwise regression starting with a model with intercept-only and adding/removing motifs at each step. The candidate motifs with a significant p-value (say for example, 0.01) for the simple linear regression coefficient β_m are retained and used by the stepwise regression procedure to fit a multiple regression model: $Y_g = \alpha + \sum_{m=1}^{M} \beta_m S_{mg} + \varepsilon_g$. Again, this stepwise regression begins with only the intercept term and at each step, adds the motif that gives the largest reduction in residual error. After adding each new transcription site, the model is checked to remove the ones whose effects have been sufficiently explained by the last added. Hopefully, this class of methods may be used to charting the regulatory circuits of all eukaryotic biochemical and signalling pathways and explaining how specific mutations serve to reprogram the ''integrated circuit of the cell'' so as to manifest cancer and other diseases.

5 Periodicities and Repeats

The studies of mechanical and structural properties of chromosomes through di- and trinucleotide models of properties, such as propeller twist, stacking energy, and curvature have shown that all bacterial chromosomes sequenced so far present a periodical pattern. Worning and collaborators have recently combined Fourier analysis, correlation, and noise reduction techniques to increase the signal to noise ratio and, therefore, detect weak periodical patterns in bacterial chromosomes. They found a periodicity of 11 bp in eubacterial genomes, while it is of 10 bp for archeal; for comparison, *Saccharomyces cerevisiae* has a dominant period of 10.2 bp. Mixtures of 10 and 11 bp periodicities provide evidence of lateral gene transfer between Archea and *Thermotoga maritima*. Audit and collaborators used wavelets to analyze bending properties of sequences and provided evidence for nucleosome patterns in human chromosomes.

The transitions from prokaryotes to unicellular eukaryotes and to multicellular eukaryotes are associated with an increase in genome size, in the organism's body size and a reduction in population size and density. The changes include gradual increases in gene number, resulting from the retention of duplicate genes, and more abrupt increases in the size and number of introns, low-complexity words, and mobile genetic elements. Simple repeats are rather rare in bacteria and in low eukaryotes and very abundant in high vertebrate genomes. Bacteria and human are at the two extremes, showing orders-of-magnitude difference in genome, body, and population size. The spreading of repeats across a genome occurred as nonadaptive when the organism size increased and the population size decreased. The selection process became less effective in determining genome size, allowing for nonadaptive processes, and more effective in controlling the phenotypic complexity. In vertebrates, if repeats are inserted in the regulatory or coding regions of genes, there is a high chance that metabolic or genetic redundancy will buffer the effect.

Repeats tend to have a GC and dinucleotide composition somewhat different from that of the DNA into which they

are inserted. Although the classification has become rather fictitious, for sake of simplicity, we can make a distinction between single-few copies, middle-, and highly repetitive DNA. Repeats in few copies are usually orthologous genes that may contain hidden repeats translated in the form of runs of amino acids and retroviruses inserted in the genome. For example, the human genome contains more than 50 copies of chemokine receptors that have high sequence similarity. Short-repetitive DNA may be placed in the highly and middle-repetitive categories. The first is formed by tandemly clustered ''satellite'' DNA of variable-length motifs (5–100 bp) and is present in large islands of up to 100 megabases and may constitute up to 40% of the genome. The middle-repetitive category can be either short islands of tandemly repeated microsatellites/minisatellites (''CA repeats,'' tri- and tetranucleotide repeats) or mobile genetic elements. Mobile elements include DNA transposons, short interspersed elements (SINEs) and long interspersed elements (LINEs), and processed pseudogenes.

Why should we be interested in repetitive DNA? Tandem repeats with 1 to 3 base motifs can differ in repeat number among individuals; therefore, they are used in population genetics and for the identification of individuals and forensic testing. It is known that trinucleotide repeats are involved in human neurodegenerative diseases (e.g. fragile X and Huntington's disease). DNA repeats increase DNA recombination events and have the potential to destroy (by insertion mutagenesis), to create (by generating functional retropseudogenes), and to empower (by giving old genes new promoters or regulatory signals). Moreover, the instability of short tandemly repeated DNA has been associated to cancer.

Particularly abundant in vertebrate genomes are strings of As and Ts that have several peculiar properties not shared by strings of Gs and Cs. *In vitro* studies have shown that such poly(A) and poly(T) sequences cannot be readily wound around the nucleosome, and this is most likely because these kinds of homopolymeric tracts have a straight and rigid structure.

The published sequence of the human genome, though yet incomplete, demonstrates that coding sequences comprise less than 5% of it, whereas repeating sequences account for at least 50% of the genome and probably even more. Many of the repeats can be found in mature mRNA and total cellular RNA. RNAs containing repetitive elements include Alu-containing mRNAs that amount to 5% of all known mRNAs.

Recently, bioinformatics has shown a link between microsatellite DNA and mobile elements. All mobile elements such as SINEs, LINEs, and processed pseudogenes contain A-rich regions of different lengths. In particular, the Alu elements, present exclusively in the primates, are the most abundant repeat elements in terms of copy number (1 090 000) and account for more than 10% of the human genome. They are typically 300 nucleotides in length and are predominantly present in the noncoding regions. Higher Alu densities were observed in chromosomes with a greater number of genes and vice versa. Alus have a dimeric structure and are ancestrally derived from the gene specifying 7SL RNA, an abundant cytoplasmic component of the signal recognition particle that mediates the translocation of secreted proteins across the endoplasmic reticulum. SINEs amplify using an RNA polymerase III-derived transcript as template, in a process termed *retroposition*. The

mobility is facilitated by a variable-length stretch of an A-rich region at the 3′ end of genomic SINE elements. Although each of the million plus Alu elements present in the human genome have poly(A) stretches, only a few are able to retropose. Therefore, the mere presence of an A stretch is not sufficient to confer on an Alu element the ability to retropose efficiently. The length of the A stretch seems to correlate positively with the mobility of the Alu.

6 Bioinformatics Analysis of Protein Modifications

Prediction and annotation of protein modifications (PMs) is a challenging bioinformatics research area because PMs have been shown to be important features for determining protein function and, since they are often involved in signalling, for systems/organismal biological studies. Main bioinformatics applications on PMs focus on prediction of the site of modifications and on database resources. Many PMs occur at specific, yet variable, motifs in the target proteins and most prediction methods use machine-learning techniques, such as support machines, artificial neural networks and HMM. Examples of prediction tools are: Ser, Thr, and Tyr phosphorylation sites in eukaryotic proteins (NetPhos), tyrosine sulphation sites (for example, Sulfinator), type O-glycosylation sites in mammalian proteins (NetOGlyc), GlcNAc-O, protein sorting signals (PSORT), mitochondrial and plastid targeting sequences (MITOPROT, Predotar, ChloroP), O-beta-GlcNAc attachment sites in eukaryotic protein sequences (YinOYang), and GPI Modification Site Prediction (big-PI Predictor, DGPI). The tendency is towards organism-specific tools, for example, glycosylation sites in *Dictyostelium discoideum* (DictyOGlyc) and protease cleavage sites in picornaviral proteins (NetPicoRNA). The field is also moving toward prediction methods specific for a class of proteins, for example, specific kinase-specific phosphorylation-site prediction, caspase and propeptide cleavage sites, and tyrosine sulfation sites. Future challenges in prediction will focus on understanding the structural features of PM sites: modifying enzymes must recognize the native three-dimensional structure around an acceptor site, and therefore, structural motifs may be more conserved than sequence motifs. Further developments will be focussed on databases and on proteomics and mass spectrometry techniques. Another important target will be understanding variation in PMs associated with diseases and developmental states; for example, it is known that glycosylation of some proteins varies in alcoholism. What we mean is that we can predict only that a site can be modified but not how likely a modified site can turn into a nonmodified one during a disease or during the developmental stages.

7 Genome Feature Classification: Gene Ontology

The overload of genome data represents a tremendous challenge for organizing and transforming results into knowledge. The Gene Ontology (GO) Consortium was formed in 1998 to provide consistent annotation of genes and gene products, and thus aid cross-species comparisons. It started as collaboration between yeast, fruit fly, worm, and mouse databases, but has since evolved to include many other

projects. The GO consortium's aim is to develop and share structured vocabularies that can be used for cross-species annotation of gene products. Currently, the GO consortium provides ontologies for three independent biological domains: biological process, cellular component, and molecular function.

1. Biological process refers to a biological objective to which the gene or gene product contributes. Some examples of biological process terms are ''protein biosynthesis,'' ''meiosis,'' and ''glucose metabolism.''
2. Cellular component refers to the part of the cell where the gene product is contained. Examples include such terms as ''ribosome,'' ''proteasome,'' and ''mitochondrial inner membrane.''
3. Molecular function is defined as the biochemical activity of a gene product. Some examples of molecular function terms are ''enzyme,'' ''transporter,'' and ''heat shock protein.''

All three ontologies are accessible at http://www.geneontology.org/. The GO Consortium also hosts annotation projects for several model organisms, including fission and budding yeasts. Gene ontology terms and relationships have been represented in the form of directed acyclic graphs (DAG). Compared with a hierarchical tree, DAG has the advantage of allowing a more specific child term to have several parent terms. There are two types of child-to-parent relationships: ''is a'' and ''part of.'' The ''is a'' relationship is used when a child represents a type of parent term, for example, cytosolic ribosome is a ribosome. The ''part of'' relationship is used when a child term is a component of the parent term, for example, cytosolic ribosome is part of cytosol. The one-to-many relationships between a gene product and ontology categories reflect the fact that a gene product may have several functions, may participate in different processes, and may interact with various proteins.

8 Limitations of Sequence Analysis

The genome is only a source of information. In order to function, it must be expressed. Differences between organisms are more related to gene expression and protein abundances than to DNA sequence. For example, chimp DNA is 98.7% identical with human DNA. If just the genes are compared, the similarity increases to 99.2%. Gene-expression levels in blood and liver of the human and chimp are quite similar but very different in the brain tissues. At the same time, many physiological variables show rhythmic changes along a time period, for example, a day, a week, a month, and a year, and it is also known that several acute diseases, such as renal colic attacks and cardiovascular diseases show a rhythmic variability as well. Therefore, future efforts will be focussed on integrating sequence data with gene expression and proteomics analysis.

DNA

Proteins

Single Molecule Biochemistry
Studies on reactions of individual molecules with each other.

Single Molecule Biophysics
Testing and handling individual molecules by spectroscopy and by nanomechanical tools.

Techniques for Single Molecule Studies
Highly sensitive techniques for handling single molecules, such as atomic force microscope tips and optical tweezers, and techniques to observe single molecules, such as optical tweezers.

Single molecule research is progressing from pure single molecule detection (SMD), for example, by scanning microscopy or by high-resolution spectroscopy, toward true single molecule chemistry, biochemistry, or molecular biology. The last few years have seen a shift from small chromophores to (biological) macromolecules. Individual protein molecules vary in structural detail and thus may have different functional properties, even if they are, in bulk, assumed to represent the same

protein. The molecule with the most pronounced individuality, however, is DNA. Theoretically, one would need oligonucleotides only 17 bp in length to assign an own sequence to each human individual. The human genome has a length of 3 billion base pairs. Such an essentially infinite variability can only be studied on a single molecule basis.

Therefore, the present review article tries to give an overview on techniques for studying biophysics and biochemistry of proteins (in Sect. 3) and DNA (in Sect. 4) without aiming to be comprehensive. In most cases, recent examples of work from representative author groups are given. Patch clamp studies, for which Erwin Neher and Bert Sakmann won the 1991 Nobel prize, will not be treated in the present overview since this field would justify a separate review.

1 Single Molecule Research: A New Era of Molecular Cell Biology and Molecular Medicine

1.1 Books and Journal Issues on Single Molecules

It is certainly just a coincidence that the dawn of a new millennium is also the dawn of a new chemistry and biochemistry. The ultimate limits in sensitivity have been achieved. Single molecule chemistry and biochemistry are now a reality. The end of the last millennium has witnessed the development of techniques, which allowed detection of single molecules in a solution or at the surface of, for example, a microscope slide. By the end of 2002, in addition to a number of reviews, a few special issues of regular journals and two books on single molecules were available in literature. The first years of the new millennium now witness the development and use of techniques to directly measure and even *modify physical properties* of individual molecules and to directly *observe reactions* of such single molecules.

1.2 Early Seminal Work and Some Recent Reviews

Surprisingly, one of the first, if not the first, single molecule experiments was not on small chromophores but on an enzyme, and it even measured reactions: It was the study on a single β-galactosidase molecule held in a microdroplet. Later, individual molecules could be manipulated with the tips of scanning tunnel or force microscopes. These techniques did not yet allow spectroscopy, since they were monochromic. Color, and thus spectroscopy, in the sense as it is typically used by the analytical chemist was not yet widely used. This problem was alleviated with the advent of the near-field scanning optical microscope and then it was realized that conventional light microscopy was also suitable for single molecule research. Then it became possible to use wavelengths of an individual molecule known from bulk analytical or physical chemistry. The 1990s were then the decade of high-resolution single-molecule spectroscopy, pushed forward particularly by the groups of Orrit, Basche, and Moerner. This development has been recently

described in several reviews. One result of such studies showed that individual small molecules behave as predicted from bulk experiments. A different situation was expected for biomolecules: since theoretical knowledge on protein structures had predicted that all individual enzymes of a species would differ slightly but distinctly from each other, it was no surprise that they revealed different reaction rates. A review on work of the type just described is essentially a precursor of the present paper and a few paragraphs from there are reproduced here. A review on its uses in cell biology has been provided by Sako, one with emphasis on single biomolecular motors is available from Ishii, and an overview of single molecule enzyme kinetics has been given by Xie.

2
Techniques for Detection and Preparation

Conventional fluorescence microscopy is surprisingly suitable for single molecule research. However, most of the other techniques required had to be specifically developed or adapted to this task. Section 2 gives a glimpse of a number of these techniques. Some of the descriptions may be somewhat oversimplified or describe only special cases of applications. Therefore, in order to fully understand these techniques in detail, the reader is referred to the specific literature.

2.1
Conventional Far-Field Microscopy: Spatial Resolution is not Required but Temporal Resolution is High

One of the biggest surprises in single molecule research was certainly the finding that normal – though high-quality – fluorescence microscopes could be used for single molecule analysis. Single molecule detection was thought to contradict the Abbe criterion, which states that the resolution of a conventional far-field microscope is not better than 50% of the wavelength of the light used for illumination (0.5 μm for green light). This was too pessimistic since resolution was mixed up with reproducibility of localization. When the molecules were prepared with sufficiently small concentration onto a surface, they had an average distance of several micrometers from each other: they had no longer to be spatially resolved but had just to be visualized. Visualization of individual molecules is possible down to sizes of a few nanometers. The price one has to pay is that the molecules appear too large, but for many applications, this drawback is acceptable. The conventional fluorescence microscope has two significant advantages, for example, compared to the high-resolution near-field techniques described in Sect. 2.6. It is fast, that is, dynamics of molecules and reactions becomes experimentally accessible and preparation techniques can be easily adapted from bulk analytical methods. Even the imaging by lifetimes, not by intensity, of single molecules is possible.

2.2
Some Remarks on Dyes and Detectors

This may be one reason why conventional far-field microscopy has got its chance in single molecule analysis. Here, light is the carrier of information and comparably gentle interactions can be used to study individual molecules. A disadvantage is that only molecules with a significant intrinsic fluorescence yield or

nonfluorescing molecules after extrinsic labeling with a fluorescence dye can be investigated. Among biomolecules, NADH, flavines, and, in the ultraviolet, proteins occurring in biological cells can be studied directly. For nonfluorescing biological macromolecules, a large number of extrinsic fluorescing dyes, that is, dyes that have somehow to be attached to the macromolecule of interest are available. Many of them are known not to or only moderately to modify the macromolecule's function. Detecting single molecules by a fluorescence microscope is not so much a problem of the number of emitted photons. Since a molecule can, in principle, emit a light quantum every 10 ns, up to 100 million quanta might be expected from a single molecule. Two problems hamper this process. First, a dye molecule will decay after a few hundred up to a million cycles of excitation and emission into nonfluorescing derivative. Second, at dilutions required for single molecule analysis, more than 99.99% of the photons are not absorbed, but may be scattered. In principle, such noninformative scattered exciting light can be separated from the informative fluorescence light by optical filters. Since the latter are not ideal, a small fraction of exciting light reaches the detector, which should only detect fluorescence from the molecule under study. Part of these problems may be overcome by replacing classical fluorescence dyes by nanocrystals or quantum dots. These are nanometer-sized clusters of, for example, zinc sulfide–capped cadmium selenide. Their absorption and emission behavior is solely determined by their size: small clusters are blue, larger ones are red. The advantage of these quantum dots is their very good absorption and emission behavior, which alleviates to some extent the problem just described. A disadvantage is their bulkiness.

When a fluorescence microscope is equipped with a standard TV-CCD camera, one can obtain 25 images per second. This corresponds to a temporal resolution of 40 ms. Special cameras are much faster; millisecond resolution is easily available when one is willing to go a step beyond standard CCD recording. For low-level light, as in single molecule research, cooled CCD cameras integrating over several image frames can be used, but then the temporal resolution is decreased correspondingly. When extreme sensitivities at high temporal resolution are required, single photon-counting cameras are available. These are, in principle, arrays of microphoto multipliers, often with 250×250 pixel elements. In almost all cases, the reduced (as compared to standard CCD cameras with 700×500 pixels) image size is completely sufficient, since single molecule observation requires only parts of a full visual field in a light microscope. Color information can be added by using a true color camera. Usually, they do not have the sensitivity described above. More efficient is the use of optical filters: fast-switching filter wheels and computer programs for exactly overlaying the different colors that are available on the market.

2.3 FRET: Foerster/Fluorescence Resonance Energy Transfer

FRET (fluorescence resonance energy transfer) can increase the resolution beyond the diffraction limit of conventional microscopy. Here, a pair of fluorescent molecules is used to measure distances of the order of 10 nm. One molecule of this pair, the donor, absorbs light and usually reemits it as fluorescence at a

somewhat larger wavelength. If, however, the second molecule, the acceptor – with an absorption maximum close to the emission maximum of the donor – comes closer to the donor than the ''Foerster'' distance, the absorbed energy in the donor is transmitted to the acceptor, which finally emits light at an even larger (more red) wavelength. Thus, a red shift heralds the mutual approaching of the donor/acceptor pair to a distance closer than the Foerster distance, which, for example, is approximately 10 nm for the dye pair Cy3/Cy5. Since typical diameters of proteins are between 5 and 15 nm, FRET experiments with this donor/acceptor pair can be used to test whether a protein molecule is folded or denatured, that is, to study protein folding on a single molecule basis. Cy3/Cy5 or other donor/acceptor pairs can also be used to study protein–protein or protein–DNA interactions as well as RNA folding on a single molecule basis.

2.4 TIRF: Total Internal Reflection Fluorescence-excitation

It is quite obvious that ideal preparations for single molecule studies should be very pure. Unfortunately, one often obtains more impurities than molecules of interest. There are, however, techniques available, which allow to focus the view only on the wanted molecules: one of them is total internal reflection. Light falling from the glass side at a very flat angle onto a glass–water interface does not leave the glass but is reflected. However, when a molecule is located directly on top of the glass, the molecule can be excited to fluoresce. Molecules and impurities at a distance of more than a wavelength are not affected. Thus, it is possible to study single molecules in a thin layer above a microscope slide without illuminating all the impurity molecules in the solution. Conventional fluorescence microscopy and TIRF total internal reflection fluorescence microscopy in single molecule research have been compared by Paige et al.

2.5 FCS: Fluorescence Correlation Spectroscopy

While TIRF confines the view into a thin two-dimensional space, FCS, fluorescence correlation spectroscopy illuminates a diffraction-limited three-dimensional volume of interest just by focusing a laser into a solution containing the highly diluted molecules to be studied. FCS requires extreme dilution of the molecules and simultaneously extreme miniaturization of the observation volume to less than a femtoliter. Basically, in such experiments, the velocity of a molecule migrating through the tiny observation volume is measured. One detects a single molecule in a given volume, and after a preset time of waiting, one looks if it is still there. Slow particles will be found several times, fast particles will be found only two or three times. Mathematically, this is described by the correlation function

$$G(t) = \text{Sum over } I(t) * I(t+T),$$

where T is the waiting time.

$G(t)$ is related to the speed of the molecule that can be used to calculate the diffusion constant of the molecule. The latter can be used to estimate the molecular weight. Such experiments are often used to measure the binding of two individual

molecules. This is possible when the two binding partners differ by at least a factor of 8–10 in size, for example, the binding of an antigen to an antibody or the hybridization of a small DNA or RNA oligonucleotide to a long DNA or RNA molecule. Binding sites of single glucocorticoid molecules on cell membranes have been studied by Maier. In such experiments, the smaller binding partner is made fluorescent. One can see the small partner as a fast diffusing object and the complex of a small with a large partner as a slow object. The correlation analysis does not only allow to obtain the absolute migrating velocities but also the ratio of free to bound molecules, that is, the binding constants according to the mass action law. The aforementioned size ratio of 8–10 is sometimes a drawback of FCS. This has, however, been overcome by two color techniques, occasionally even combined with FRET.

2.6 Near-Field Microscopy (Scanning Tunneling Microscopy, SNOM, AFM)

Extremely high resolution can be achieved with near-field techniques. All the near-field microscopes work according to a common basic principle: A sort of ultra fine stylus scans an object line by line and subsequently assembles an image from the data it has obtained. This data assembly takes some time and therefore the temporal resolution of these microscopes is limited to seconds or below seconds (see, however, Sect. 3.5). In turn, the spatial resolution is better than with any other tool available to the analytical chemist or biochemist. The reason for this is that the stylus comes very close to the object under observation. It is the same principle as the stethoscope of a medical doctor: For example, acoustic waves of a beating heart with wavelengths of meters can be exploited to localize the heart with an accuracy of centimetres. Therefore, the optical version of the near-field microscopes, the SNOM (scanning near-field optical microscope) has also been also called *optical stethoscope*. It has a typical spatial resolution of 60 to 80 nm and can be used as a highly localized spectroscope. The second near-field microscope used in the analysis of single biomolecules is the atomic force microscope, AFM. Here, a mixture of van der Waals, electrostatic, and other forces are used to detect the molecule. Since these are all short-range forces, one has to get closer to the molecule under observation and the spatial resolution with the AFM is better than with the SNOM, for ideal (hard) objects in the subnanometer range. Even the combination of an AFM with a confocal laser scanning microscope is available. The near-field microscope with the best resolution is the scanning tunneling microscope, (STM), which, under favorable conditions, can detect submolecular structures. It needs electrically conducting objects and is therefore not generally suitable for single biomolecule studies. Interestingly, the most successful use of near-field microscopes is meanwhile not imaging, but manipulation. The tip of an atomic force microscope is used as an extremely fine manipulator for handling individual molecules and for measuring forces in macromolecules such as proteins, RNA, and DNA while stretching the latter. If one exerts such a force on molecules bound to each other, force-extension curves can be obtained, which show a break at some specific force. This force, however, is not sharply defined. In fact, one obtains a probability curve with a most probable force of a few hundred piconewtons and a full width at half maximum of 50–100 pN. AFM tips can now

be prepared with an individual atom as the active tip. Sections 3.2, 3.3, and 4.3 give a detailed account of AFM tip experiments with biomolecules.

2.7
Manipulation with Nanometer Accuracy Laser Micromanipulation for Handling of Individual Macromolecules

The tip of an AFM is best suited to apply and to measure forces from a few hundred piconewtons up to a nanonewton (for comparison: millions of such AFM tips would be required to lift 100 mg at the surface of the earth. If gentler handling or sensitive force measurement is required, optical tweezers are the tools of choice. Optical tweezers are made of a continuous (often infrared) laser of moderate power, which is focused into a microscope to the theoretical (diffraction) limit. Light pressure and gradient forces push and pull microscopic objects in the focus of the laser. By moving the focus, these objects can be moved along complex trajectories. Since only forces exerted by light are acting, no sticking of individual molecules to microtools such as AFM tips or disruption by the latter occurs. As with AFM tips, mechanical properties of biomolecules can be measured with optical tweezers. Optical tweezers are also used as stylus, similarly as in the near-field microscopy, to detect force landscapes on the surfaces of soft objects such as cells. This technique has been dubbed ''Photonic Force Microscopy.''

3
Proteins

For some biological macromolecules, the individual differences are not only just interesting for reasons of basic research. Such differences may be important for health and disease. For example, the malfunction of an enzyme may cause irregularities. Such a malfunction may develop by a sort of evolution and may only gradually turn into a true disease form. Early detection of such changes on the single molecule basis will probably allow early diagnostics and thus, may help prevent the outbreak of a disease.

3.1
Spectroscopy on Single Biomolecules

An obvious step toward single molecule research is just to increase the sensitivity down to the single molecule limit, even with Raman spectroscopy when surface enhancement is used. One protein molecule of particular interest is the green fluorescent protein GFP, since it's mRNA can be fused with the mRNA of another protein. After *in vitro* translation, the combined protein often preserves the function of the fused protein, but is now fluorescing and its action, for example, inside a living cell, can be studied. Therefore, the spectral properties of GFP are of special interest and have been studied correspondingly on a single molecule basis. An interesting class of proteins are light harvesting molecules that convert the energy of light into chemical energy. Complex energy conversion processes have now been understood on a single molecule basis. The most straightforward study of macromolecular structure is possible if these molecules change their spectroscopic behavior as a function of conformation. Such a molecule is the (nonbiological) MEH-PPV, a conjugated phenylene-vinylene polymer.Huser et al. could demonstrate that single MEH-PPV molecules have a conformational memory when cast from toluene, but not

when cast from chloroform, where they behave as multichromophore systems. Unfortunately, biomolecules do not reveal such an intrinsic structure–spectrum relationship and here dye molecules have to be attached for folding studies. FRET (see Sect. 2.3) may be the technique of choice. While a number of proteins, such as crystalline from the eye lens, spontaneously fold into their correct three-dimensional structure, many others need the support from partner proteins called *chaperones*. GroES and GroEL are such proteins, and their interaction is essential for protein folding in the bacteria *Escherichia coli*. Using Cy3 and Cy5 as FRET partners, Taguchi et al. could show that both molecules bind with kinetic constants known from bulk experiments. However, only the single molecule experiments could reveal that the two molecules remain in contact for approximately 3 s. This is the time a target protein has left in order to fold into its correct structure.

3.2 Force Spectroscopy on Selectin, Titin, and von Willebrandt Factor

An even more detailed insight into individual macromolecules is possible with force spectroscopy. Here, the tip of an atomic force microscope is used as a nanomechanical tool. One end of the molecule is attached to a surface, the other end to the AFM tip. Then the tip bound end is pulled and the tip bound end is pulled and the force that is required to pull the molecule apart is measured. Also, the force acting between two molecules can be studied. This technique has been applied to many molecules; one among them is DNA, which will be discussed later. One example is P-selectin-ligand binding, a molecule pair that mediates adhesive interactions in immune recognition and also in metastasis of several cancer types. Forces up to 175 pN, that is, one-fifth of a covalent bond, can act. The rate constant for unbinding may vary from $0.2\ s^{-1}$ to $2.8\ s^{-1}$. Such a pronounced difference explains different adhesion behavior of the cells that use P-selectin. A molecule with similar function is fibronectin. Its mechanical properties are critical to the elasticity of the extracellular matrix and connective tissue. Oberhauser et al. have found an extreme extensibility of this molecule. The molecule has a hierarchical force profile, indicating that it has different building blocks with different mechanical stability, particularly its FNIII region.

The von Willebrandt factor is a protein involved in many aspects of protein clotting in blood. Occasionally, it comes in ultralarge aggregates (ULVWF), particularly in catastrophic microangiopathic disorders. Using optical tweezers, Arya et al. could show that specific conformations, and not so much the size of the aggregates, is critical for the interaction of ULVWF with platelets – cells that mediate the generation of thrombi in blood.

Titin, a tandem array of fibronectin and a sort of immunoglobulin, is anchoring the motor protein myosin of muscle to elements of the skeleton. If a muscle is slightly overstretched, titin dampens the forces and reversibly unfolds. Only after strong over–stretching, the muscle is hurt. Owing to this importance, titin is among the molecules best investigated by single molecule force spectroscopy. Just to mention one work, Grama et al. have labelled titin with the fluorescing rhodamine, which, owing to self quenching when two rhodamines are approaching each other, act similarly as the donor/acceptor pairs described earlier. Surprisingly, chemical denaturation

of titin leaves the titin molecule intact, perhaps since acidified muscles need to keep their mechanical stability.

3.3 Single Molecule Immunology: Antibodies and Antigens

A particularly interesting field is single molecule immunology. The binding of an antibody to its antigen is a crucial step in the response of the immune system to infection. Therefore, knowledge on binding constants and forces between antigen and a given antibody gives information on the efficiency of the immune response of this antibody. Several techniques have so far been used to study this process. In a methodical work, Tetin et al. have shown that the equilibrium dissociation constant of an antibody against the test antigen digoxin yields the same value if fluorescence polarization or FCS is used, that is, both techniques are suited to determine such constants. A disadvantage of these techniques is that they are performed in solution, while typical antigen antibody reactions occur at surfaces. Such surface studies were performed by Seeger et al. and Li et al. With tapping mode atomic force microscopy, they monitored the binding constant of two different antigen/antibody pairs at near physiological conditions in molecular monolayer consisting of the antibodies. The binding constants were essentially determined by counting the ratio of antibodies with and without the bound antigen. This technique is obviously also suited to evaluate antibody microarrays. Since the Y-shaped antibody molecule has two binding sites for an antigen, it is interesting to know whether both act independently or cooperate. This question has been tackled by using an AFM simultaneously as a microscope and a tool to measure forces. The unbinding force for an antibody against serum albumin has been measured as 244 ± 22 pN and an action of both binding sites independent of each other has been detected. The binding to individually addressed antibodies has been measured by Ros et al.

An interesting technical approach has been presented by Jermutus et al. The authors coexpressed and cotranslated single-chain antibody Fc fragments with ribosomal mRNA, that is, they displayed them on these large molecules. Then they could study the antigen binding on a single molecule basis using FCS and determine kinetic constants of that process with good statistics.

3.4 Molecular Motors

Molecular motors are molecules generally converting chemical energy into motion. Some small organic molecules are known to act as motors. They will not be discussed here. (Bio-) molecular motors govern processes characteristic of the life of cells and organisms, such as generation of motion in eukaryotic cells, cell division, cell movement, segregation of genetic material, or positioning of organelles. Owing to their fundamental function biomolecular motors are used as therapeutic targets (e.g. taxol treatment in cancer chemotherapy.) Linear motors move along filamentous macromolecules or macromolecule assemblies, which act as a kind of track. Prominent examples are kinesins and dyneins, which belong to motor families with more than one hundred members generating motion along microtubules by hydrolyzing ATP as a fuel. Another motor is myosin in its numerous variants, well known for generating motion along

actin microfilaments and thus, contributing critically to muscle contraction.

The motor proteins kinesin, dynein, and myosin consist of an elongated stalklike tail and one or two globular heads binding ATP as well as microtubules respectively to the actin microfilaments. Upon ATP consumption, they undergo conformational transitions connected with walking along the filamentous tracks. Thereby, the angle between the tail and the head is changed causing, if bound, a stroke driving the head forward in relation to the track. After such a stroke, the head is released, swings back to its ''starting'' position, binds to a new site on the track, and is loaded by the new ATP. The process is ready for repetition. In principle, most of the related questions to motor function and regulation can be answered by bulk experiments comprising some or many motor molecules. For example, the force generated by a muscle filament can be measured macroscopically. The number of myosin molecules involved in this process can be determined and allows to calculate force generation per myosin molecule. But one problem arises immediately: The duty ratio, that is, the ratio of the active period of the motor to the whole molecular cycle. It represents the fraction of molecules of a collective, which is involved in force generation at any given instant. Depending on the model used, the duty ratio can be estimated in the range between 5 and 90% – resulting in a factor of 20 in uncertainty. Therefore, it is essential to measure these mechano–chemical processes on a single molecule basis. One way to measure single molecule mechanics is to use fine glass microtools, contributing, however, to inherent problems such as adhesion and perturbation of the tiny forces involved. Optical tweezers are a second tool for single molecule motility research, allowing evaluation of both techniques against each other. Owing to the high interest in these questions, a large number of single molecule experiments have been described in early literature by the groups of Block, Molloy, Schliwa, Sheetz, Simmons, Spudich, Warshaw, and Yanagida.

More recently, Nishiyama et al. studied the chemo-mechanical coupling of forward and backward stepping of kinesin. They formulated a model where the driving force for motion along the microtubule is Brownian motion and where the energy is primarily used to decrease entropy, that is, by giving this motion a direction. In similar experiments, Gross et al. have investigated dynein and the related molecule dynactin, which can move bidirectionally along microtubules. The authors postulated that dynactin enables dynein to participate efficiently in this bidirectional transport. Rock et al. reported that Myosin VI is a highly processive motor with very large step size. The maximum step size reported so far is 35 nm for higher plant myosin XI. Baker et al. provided the basis for understanding the ATP reaction, which provides the energy under minimal load. They found that the dissociation of one phosphate group is more closely related to the generation of motion than could be demonstrated before. The work of Peterman et al. put forth the idea that single molecule studies may be related to the multimolecule interaction in real life in kinesin. These authors compared the relative orientations of monomeric and dimeric kinesin and showed that both kinesin molecules have to bind with similar orientation in order to reveal optimal activity. Among others, such investigations predict that biomolecular motors are active to transport artificial loads, which can be regulated and tuned

under cell free conditions and that they are able to work in predetermined directions.

As for technical motors, rotatory molecular motors also exist. F1 ATPase is a representative member of this class of molecular motors and converts chemical energy of ATP into rotation. Interestingly, it can also perform the task in reverse: when rotation is induced by exerting force on the molecule, it converts the low-energy ADP into high-energy ATP, that is, it converts mechanical into chemical energy. In a typical experiment, a fluorescence-labeled actin filament is bound to one of the subunits of the F1 ATPase. The ATPase is fixed to a surface. The actin filament can be easily observed by fluorescence microscopy and manipulated by micromechanical tools or optical tweezers. If left free and supplied with ATP, the ATPase rotates. This can be observed by rotation of the actin filament. A study of this type is, for example, that of Kato-Yamada.

3.5 Visualizing the Action of Individual Dynein and Myosin V Molecules in Real Time

Probably the most exciting recent development in single molecule research results from the possibility to obtain movies from working individual molecules. This does not mean the somewhat indirect visualisation of molecule action as described in the previous section. Meanwhile, it is possible to have a direct look on the dynamics of individual biomolecular motors. Burgess et al. have organized a temporal series of electron microscopic snapshots of dynein c molecules into a sequence of events, which allows to reveal how dynein generates motion along microtubules. They could show, that the stalklike tail performs structural changes, which may be required to generate motion. Even more exciting are the results of Ando et al.; using a homemade atomic force microscope with a temporal resolution of 80 ms, that is, half the frequency of commercial TV video. These studies with myosin V directly reveal that the stalk of the myosin molecule is very flexible and that there are changes in lengths of this arm, indicating, similarly as the dynein data, that structural changes of this part of the molecule, and not so much changes in the relative orientation of the heads of these molecules, generate motion. Thus, the mechanisms developed in the more indirect experiments described in Sect. 3.4 may need some modification in order to allow for these recent observations. Figure 1 shows the sequence of events for the myosin.

3.6 Single Molecule Enzyme Kinetics

From conventional biochemistry (enzyme concentrations 10^{-9} mol ml^{-1} or

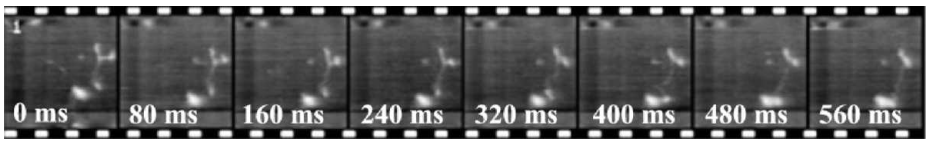

Fig. 1 Time series of myosin molecules in action (reproduced from Ando 2003). The motion of the Y-shaped myosin molecule is shown in steps of 80 ms. The molecule performs two types of motion: it slightly rotates as a whole and it's stalk changes length. These changes in shape are not completely consistent with the models derived from more conventional experiments and require that the latter should be modified accordingly.

10^{13}–10^{14} enzyme molecules), the step to the single molecule range involves an increase in sensitivity of at least 13 to 14 orders of magnitude. In recent years, enzyme kinetics has been developed down to the single molecule level. The conformational dynamics and cleaving mechanisms of enzymes have been directly observed at surfaces. The group of Xie has used the natural fluorescence of cholesterol oxidase, which is fluorescent in its oxidized form. As the reaction proceeds the enzyme oscillates between the oxidized and reduced states, that is, it blinks. Each blinking corresponds to one enzymatic turnover, which was followed with time. Also, fluctuation of reaction rates of one cholesterol oxidase molecule was observed. Earlier, Dovichi and coworkers had used a similar approach to confine single molecules of alkaline phosphatase and to measure the reaction products completely inside a capillary. A clinically interesting enzyme is lactate dehydrogenase (LDH), since it is used in the diagnostics of heart attacks. Xue and Yeung studied this reaction at selected substrate concentrations in a capillary tube equipped with a LIF detector and found different activities for individual molecules. As an alternative, the ''droplet in substrate'' technique, where the reaction proceeds at the surface of a highly viscous droplet containing a few LDH molecules, which was previously injected into a substrate solution allowed very detailed studies on this reaction. The conversion of nonfluorescing NAD+ into fluorescing NADH by individual molecules of LDH has been observed by this approach. Quantized reaction rates have been found. The rates were multiple integers of a basic reaction rate. This was interpreted as the reaction catalyzed by one, two, and so on, up to six enzyme molecules.

3.7 Single Protein Molecules in Viruses and in Living Cells

Single molecule research reaches even deeper into cell biology and thus life. A number of groups have been successful in imaging individual molecules on the surface of cells and even inside cells. An important step in such studies was the development of techniques to study the diffusion of individual molecules and the understanding of the influence of nearby surfaces close to diffusing molecules. The insertion of dye molecules into model membranes has been reported by Milhiet. Protein molecules, which usually reside in the cell membrane, have been incorporated into artificial membranes and their behavior could be studied there. Sub-wavelength resolution colocalization of individual dye molecules was reported by Heilemann. Also, on living cells the binding strength of single fibrinogen-integrin molecule pairs have been measured by allowing cells to get into contact and then measuring the acting forces. With optical tweezers, the binding strength was measured to range from 60 to 100 pN. Since the cells used in these studies, platelets, play a pivotal role in blood clotting, such information is of importance for understanding the basic features of the generation of heart attacks and may possibly give hints for strategies for the prevention of these catastrophic events.

Smith et al. have shown how the Phi 29 portal motor protein packs the 6.6 μm long double-stranded DNA molecule, which contains the genome of this virus against a force of more than 50 pN into the protein capsid of this virus. A corresponding theory on these processes is also available. But even the infection of individual

cells by individual adeno-associated virus particles has been directly observed by fluorescence microscopy. Comparing the reaction paths and speeds of many individual virus particles from the surface of the target cells into the nucleus it could be shown that there are preferential reaction paths and that the average infection time is approximately 12 min, however, with a large deviation among individual virus particles. Also, with the aim to study how the mono-cellular slime mold *Dictyostelium discoideum* reacts to chemotactic attraction, the binding of c-AMP molecules to different sites on the surface of these cells has been studied. The probability of individual association and dissociation events was greater for receptors at the anterior end of the cell, that is, the side into which the cells migrate. Particularly exciting is the possibility of ''harvest'' molecules, which are just passing a pore between cell nucleus and cytoplasm using an AFM tip. This has been accomplished by Oberleithner et al. with eggs from the frog *Xenopus laevis*. The motion of β-galactosidase molecules through 3T3 fibroblasts has been reported by Kues. This working group has also shown how to observe the motion of single molecules perpendicularly to the observation plane (the z-direction) of a microscope, a very important technique to observe single molecule signaling in a cell from its surface through the nuclear membrane into the cell nucleus or vice versa.

4
RNA and DNA: Highly Individual Molecules

4.1
Individual DNA Molecules as Construction Material and Electric Wires

Molecules have electric properties such as a resistance. For example, for single octanethiol molecules, a resistance of 900 ± 50 megohms was determined on the basis of more than 1000 individual molecules. Such properties are particularly interesting for DNA, of which a number of physical properties are known. This has led to the suggestion to use DNA as mechanical construction elements. Csaki et al. have shown how highly addressable single DNA molecules can be used as building blocks to construct molecular nanostructures. Two DNA molecules interact (hybridize), when their sequences are complementary. For example, if a DNA molecule has a sequence GAATCT at its end, it may bind to a sequence CTTAGA of a second DNA molecule. If two such molecules are brought into a specific geometric configuration, for example, with the tip of an AFM or with optical tweezers, complex nanostructures can be constructed with very high accuracy. The binding sequence with six DNA bases used in the example above has a length of only 1.8 nm, since the distance from ''letter'' to letter'' of DNA is only 0.3 nm (3 Angstrom). Usually, in literature it is assumed that DNA can be directly used as an electric nanowire, since earlier experiments have found electric conductivity of DNA. This concept is, however, challenged by a paper of Gomez-Navarro et al. These authors have carried out two experiments: they have measured the charge transfer from an electrode to the single DNA molecule and they have measured the dielectric response, when the molecule has no contact to any electrodes at its two ends. The authors found high resistivity of DNA, comparable to mica, glass, or other electric insulators. DNA can even be used to generate motion. Such a nanomechanical device has been presented by Mao et al. Since the two structural variants of DNA, the B and the Z form, have different length

and are differently thick, the induction of a B-Z transition by changing the salt concentration may be used to induce motion in such a DNA construction network. Knots have been tied with DNA molecules and DNA molecules have been suggested to be used as molecular tweezers. Even when nanostructures are constructed from materials such as carbon nanotubes, single DNA molecules may be helpful as stabilizers of the structures.

4.2 Stretching and Folding RNA, DNA, and Chromatin

The step from the use of DNA as construction material to single molecule DNA biophysics is not large. While the B-Z transition described in the previous section can be induced physico-chemically, structural transitions in DNA can also be induced by exerting forces. In physiological environment, that is, at salt concentrations around 150 mM, DNA tends to collapse into a globular structure. With forces of the order of 10 to 20 pN, the DNA molecule can be extended into the normal structure with a length of about 0.3 nm per base pair. At forces between 20 and 60 pN, the DNA molecule is reversibly overstretched up to the 1.7 fold of its ''natural'' length and is occasionally termed S-DNA. Above 60 pN, irreversible overstretching will occur. Similar effects are seen with double-stranded RNA. Using the tip of an AFM, Bonin et al. have investigated its flexibility. They have found a conformational change similar to the DNA B-S transition, but overstretching is possible up to a factor of two.

The folding of single-stranded RNA is different and comparable rather to protein folding. Indeed, some single-stranded RNA molecules fold into structures with enzymatic activity (ribozymes). Using single molecule FRET, Russell et al. have shown that folding occurs in deep valleys of the folding landscape, that is, along very stable pathways. Interestingly, the temporal sequence of folding is very critical. If long-range contacts are made at the right time, they stabilize a structure, otherwise they may destabilize it. With similar techniques, Onoa et al. could show that the *Tetrahymena thermophilia* ribozyme has eight different folding barriers. Forces of 10 to 30 pN are required to overcome these barriers.

Similar techniques are used to study the stability of nucleosomes and of chromatin, the structures in which DNA is usually present in living cells. When a piece of chromatin consisting of DNA is wound around, the nucleosomes are stretched, in a first step 76 bp are released at low stretching force. When the force is increased, additional 80 bp are released in two stages. In a reverse experiment, Leuba et al. studied the assembly of nucleosomes and chromatin. They found a strong inhibition of assembly at forces as low as 10 pN, indicating that DNA needs its full flexibility to wrap around the nucleosomes.

4.3 DNA Melting and Zipping: Separating and Joining the Two Strands

A considerable wealth of information on the double-stranded DNA duplex can be obtained by pulling apart the two strands. To achieve that, one end of the molecule is attached to a surface. Of the other end, one strand is also fixed to some point while the second strand is attached to an AFM tip or a bead that may be manipulated by magnetic or optical tweezers. Force can then be used to separate the two strands of DNA. Stretched unwound DNA denatures locally even at comparably low forces of

2 pN. However, for complete separation of short double helices, 17–40 pN are required to overcome the energy barrier for rupture of 9–13 kcal mol^{-1}. Unzipping (or melting) can also be induced by high temperature. In combination with pulling the molecule, such a melting can be actively induced, and the DNA denaturation–renaturation kinetics can be studied. The *T*4 gene 32 protein gp32 specifically binds to single-stranded, that is, molten DNA. With single molecule force spectroscopy, it was shown that, surprisingly, gp32 does not reduce, as expected, the melting temperature, but affects the kinetics of this process. Danilowicz et al. found multiple metastable intermediates when lambda phage DNA molecules were unzipped. Unzipping changes pace in a sequence-dependent manner. Not only unzipping has been observed on a single molecule basis. Also, the rejoining of individual DNA strands can be observed on a single molecule basis. A single nanopore, made of alpha hemolysin, is required. By this approach, the binding of an octanucleotide to its complementary DNA strand has been observed with techniques derived from patch clamping. In spite of the complex environment, kinetics and binding constants for duplex formation were comparable to those of bulk experiments. This is an example, where single molecule experiments do not provide essentially new information, but confirm that bulk experiments provide useful data to understand the single molecule process.

4.4 Replication, Transcription DNA Repair and DNA Mapping

In Sects. 4.1 to 4.3, biophysical studies were reported. The step to biochemistry or molecular biology is represented by single molecule studies on enzymes working on DNA, particularly polymerases, enzymes involved in DNA replication and repair. A second sort of enzymes, endonucleases, will be discussed separately in Sect. 4.6. Occasionally, it is single molecule research that detects the true inherent complexity of polymerases, the enzyme class that synthesizes RNA from the DNA blueprint. Individual molecules of RNA polymerase reveal a surprisingly uniform kinetics, in contrast to some predictions derived from protein folding theories, from which significant differences were forecasted on the basis of structural heterogeneity. Obviously, evolution has selected, from the variety of possible structures, only those that reveal optimal function. Such a polymerase does not polymerize the RNA continuously, but pausing can be detected. When the template DNA molecule is stretched, this pausing can be modified and thus, studied in more detail. In a similar way, it has been shown that the rate of DNA replication slows down when the DNA molecule is stretched with a force of up to 20 pN. Above this force, replication completely ceases. In order to observe reactions combed DNA can also be used, that is, DNA stretched on the surface of a microscope slide. Topisomerases, that is, enzymes that are involved in the unwinding of DNA have been studied on a single molecule basis by Strick et al. and Dekker et al., nucleotide excision repair by Segers–Nolten. The question of how enzyme molecules find DNA and keep contact during catalysis is of major importance for maintenance and replication of the genome. The binding domain of Tc3 transposase, for example, when stained with the fluorescence dye tetramethyl rhodamine (TMR) fluctuates between a fluorescent and a quenched form, when

bound to DNA Daniel et al. Also, a so far unsolved or at least heavily disputed question asks for the mechanism of enzymes at work. Jiao et al. have detected, by time lapse atomic force microscopy, two modes of target recognition between the tumor suppressor protein p53 and a DNA fragment containing a recognition site for this protein: direct binding and initial nonspecific binding with subsequent one-dimensional diffusion of the protein along the DNA to the specific site. Even more important, polymerases or nucleases work on long DNA molecules, repeating a catalytic step many times. Polymerases have to add nucleotides step-by-step, nucleases have to remove or cut them. The question is then, for how many steps an enzyme molecule repeats this task, that is, how long does it stay attached to the individual DNA molecule. This has been discussed under the aspect of processivity. A number of these questions have been solved with ingenious interpretations of bulk experiments, but the final answer can only be obtained by direct observation of single molecule reactions. Harada et al. have shown in real time how a RNA polymerase molecule proceeds along a stretched DNA molecule for approximately 1 μm. In these studies, the DNA molecule remained unstained and the enzyme molecule was fluorescence labeled, so that one could observe a fluorescent spot running along an invisible linear track. In a similar study, however, with restriction endonucleases, the opposite strategy was employed: The DNA molecule was fluorescence labeled and the action of the enzymes was observed by the cuts they induced. Since, the cuts in Fig. 2 are temporarilly consecutive, (see time at the bottom of each figure) one can conclude that one enzyme molecule remains attached for several micrometers and induces sequentially all visible cuts.

4.5 Single Molecule DNA Sequencing

Probably, one of the most exciting potential applications of single molecule research is the sequencing of DNA. The idea was fostered by the early success to observe the enzymatic degradation of the molecule. Unfortunately, full single DNA molecule sequencing, after a decade of research and even after human genome sequencing has been completed, has not lived up to its promises. The principle idea is straightforward: Using an exonuclease, which digests DNA from one of its end base by base, a flow of single nucleotides through a detection volume is generated. By identification of the sequence of the single individual DNA bases flowing through this volume, the sequence of the DNA macromolecule, held in position by optical tweezers or an AFM tip, can be determined. Two problems have so far hampered this approach. As for all other optical detection techniques in single molecule research, fluorescence is needed. Unfortunately, at room temperature, DNA bases reveal a notoriously low fluorescence yield, four to five orders of magnitude lower than typical fluorescence dyes that have an yield of some ten percent. A few attempts to work in the cold at nitrogen or even helium temperatures have so far not been successful, since the digestion-enzyme reaction has to be performed at room temperature while detection has to be performed in the cold, and the sharp change of temperature has so far not yet been managed. The alternative, to attach sequence-specific fluorescence dyes, is exceedingly more difficult than in the examples described above, since for DNA sequencing, each DNA base has to be labeled and the overall yield of labeling has to be 99.9% in order to

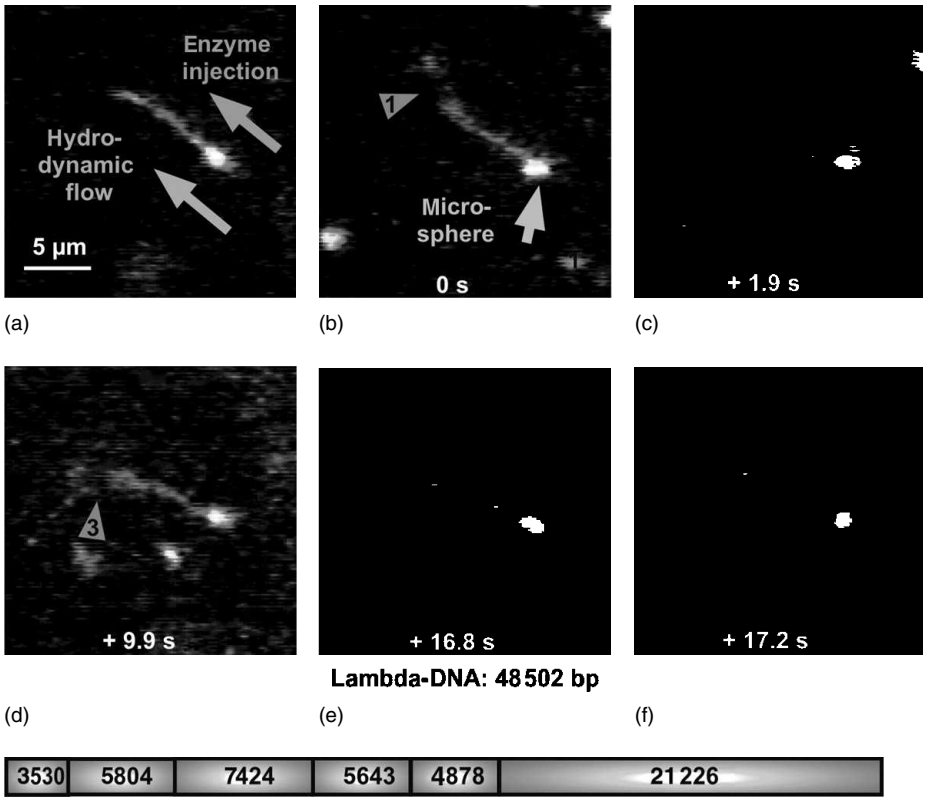

Fig. 2 Cutting of a single ''lambda phage'' DNA molecule, which is held by optical tweezers, into a sequence-specific pattern, The DNA molecule is stretched by hydrodynamic flow, otherwise it would collapse into a globular structure. The Eco R1 molecule attaches with highest probability ''downstream,'' which can be explained by a geometric shadow effect. Then it searches for it's first recognition sequence and cuts. It remains on the molecule and continues to search until all five restriction sites are consecutively cut. Cases in which the enzyme molecule binds not absolutely downstream, and cases in which the enzyme molecule falls off with the DNA fragment are also observed but represent the minority of events.

be competitive with conventional DNA sequencing. The labeling reaction has to be template directed, that is, to be a sort of DNA amplification. Once such a reaction is required, one can, however, easily amplify the single DNA molecule a million times and they perform conventional sequencing. The latter strategy indeed has been successful and is occasionally referred to as single molecule DNA sequencing. The original approach of direct sequencing, however, has remained just a concept.

4.6 DNA Analysis by Mapping and Restriction Fragment Sizing

In the mapping of individual DNA molecules, megabase-sized DNA mole-

cules are stretched and attached to the surface of a microscope slide and short kilobase-sized fluorescent DNA molecules are bound (hybridized) in a sequence-specific manner to the long target DNA. Such a mapping can also be combined with two-photon imaging. One will find a fingerprint-like sequence-dependent pattern of fluorescence spots. For the preparation of a large number of target molecules, molecular DNA combing has been developed, a technique in which many DNA molecules are stretched and paralleled by the receding meniscus of an evaporating microdroplet. Combed DNA can be used for mapping of a large number of parallel molecules. These authors could quantify the number of single gene copies on genomic DNA. A fluid flow technique, similar to the one described in the preceding section, has been used to characterize DNA fragments after application of ionizing radiation. The fragments are flowing away and can be quantified in a distant observation volume as fluorescent bursts. Anazawa et al. have presented a study on electrophoretic quantification of single DNA molecules, and Foquet et al. have performed fragment sizing in submicrometer sized fluidic channels. Fragment sizing can, however, also be used to get sequence information and thus to characterize individual DNA molecules. As in sequencing, the individual DNA molecule is held in position by optical tweezers and is stretched hydrodynamically or electrostatically. Then the molecule is cut into different fragments by sequence-specific restriction endonucleases, quite similar as it is done in bulk DNA typing to solve, for example, criminal cases or to perform paternity tests. The fragments have sizes that reflect the sequence of the individual DNA molecule.

Probably, the most detailed study uses nonspecifically labeled DNA and is a continuation of the basic study on sliding and hopping described in Sect. 4.4. Figure 3 shows, for DNA from the bacteriophage

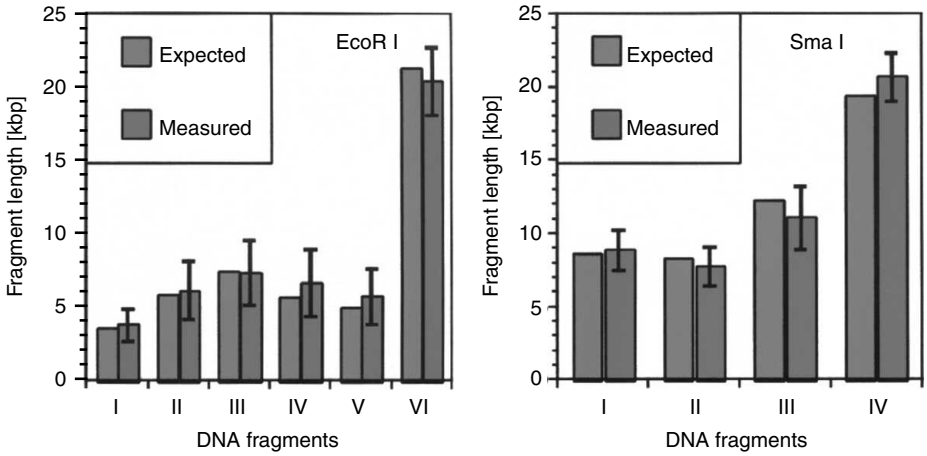

Fig. 3 Determination of the size of the restriction fragments: The fluorescence of the fragment is set in relation to the fluorescence of the whole molecule and then multiplied with the length of the latter, 48, 502 bp (red). The green columns are the values expected theoretically on the basis of the sequence of the molecule and the recognition sequences of the two enzyme molecules used, Eco R1 (left) and Sma 1 (right) (See color plate p. xxv).

Lambda, the sizes of the DNA fragments detected by this approach (green columns) as compared to the sizes expected from the sequence. The accuracy of individual fragment sizes is lower but comparable to those from conventional bulk experiments using 10–15 orders of magnitude more molecules. Individual DNA molecules can be safely characterized.

A particularly original strategy for DNA restriction uses unzipping of the double-stranded DNA molecule. If the two strands of a double-stranded DNA molecule are pulled apart with AFM tips, force is needed. At positions where restriction endonuclease molecules are bound to their recognition site on the respective DNA molecule, the force required abruptly increases and then decreases. This pattern of force peaks can be used to assemble a restriction pattern with an accuracy of approximately 25 bp.

5 Summary and Outlook

Single molecule techniques are now fully developed and used in the study of biological macromolecules. Since biomolecules have their own individuality, single molecule research is more than just a tremendous increase in sensitivity of 10 orders of magnitude. It opens the door to study the full width of variability in the living world.

Keywords

Autosampler
Automatically takes sample from the PCR plate, places the sample in the injector valve, and injects the sample into the mobile phase flowing to the column.

Chromatography
Literally ''color writing,'' a term describing a separation technique that occurs on the basis of the difference of interaction of sample components with two phases: a stationary phase or a column and liquid mobile phase or eluent, sometimes called *HPLC* or *high performance liquid chromatography*.

Column
Typically a tube of sorts that contains the stationary phase or column packing of a chromatographic system, usually consisting of nonporous, polymer-based particles chemically bonded with a C18 chemical functional group.

Detector
One of the basic components of a DNA chromatographic system; responsible for providing the presence and amount of separated sample components as they pass through the flow cell.

Eluent
Another term for the mobile phase used to carry out a separation.

Gradient Elution
An HPLC procedure where the composition of the mobile phase increases in strength during the separation; a typical example is where the mobile phase starts out as water with a low concentration of acetonitrile and more acetonitrile is added continuously as the separation proceeds – increasing the amount of acetonitrile in the eluent makes it stronger, and sample bands leave the column sooner.

Fluorescence Detector
Device using excitation light to induce fluorescence of tagged nucleic acids as they elute from the column; advanced fluorescence detectors may excite and detect up to four different tags simultaneously.

Ion Pair Chromatography
A chromatographic method in which the sample ions are ''paired'' with the opposite charged agents, thus forming a neutral ion pair and allowing the sample to be retained on a nonpolar, reverse phase column.

Mass Spectrometry Detector
A chromatographic detector in which sample components are ionized and resolved on the basis of their mass to charge (m/z) ratio because of their behavior in electric and magnetic fields.

UV Detector
The most popular form of detector used in DNA chromatography based on the absorption of UV light by the nucleic acid fragments typically allows operation at any wavelength from 190 nm to near 380 nm, with the most popular setting at 260 nm (or 254 nm) for single wavelength detectors.

DNA chromatography is the high performance, automatic separation, and purification of nucleic acids by liquid chromatography. It is an analytical technique not widely understood nor widely used by the molecular biologist, but has tremendous power.

The needs in molecular biology science are changing rapidly. In order to understand and ultimately control the molecular basis of life, complex experiments must be designed and large numbers of samples must be analyzed. Stated differently, the molecular biologist must become more analytical. New analytical tools must be implemented, and analytical information must be generated and studied.

Because of the inherent analytical nature, DNA chromatography has the potential to become one of the leading analytical tools used by the molecular biologist. Fortunately, the technology and methods have been designed so that it is not necessary for a molecular biologist to become an analytical chemist in order to perform the work. However, it is necessary to understand some of the concepts that are the basis of the technology and to understand where and how it can be implemented. It is the intent of the authors that this article should help molecular biologists how to use DNA chromatography effectively in their research.

1 General Overview

1.1 Historical Review and General Applications

The knowledge base of molecular biology has been built upon the use of analytical tools. The success of any particular tool depends on how well it can perform its analytical function – for example, is the tool and method accurate, fast, and reproducible, and does it perform the task that is needed? One of the mainstay tools used in molecular biology is the

separation, quantification, and purification of nucleic acids.

Chromatography or high performance liquid chromatography (HPLC) is a column technique where samples are introduced to one end of the column and are separated as they are carried through the column by a fluid (the eluent) being pumped through it. The separation is monitored with a detector, and separated materials are collected if desired. A special variation of the chromatographic method is DNA chromatography, where large quantities of nucleic acid fragments can be introduced, separated, detected, purified, and collected through computer-controlled instrumentation. The collected DNA may be used for downstream processing techniques such as cloning, PCR, or sequencing.

With the introduction of high performance columns, modern DNA chromatography separations were achieved. This technology has been applied to a wide variety of applications, including quantitative PCR product analysis, cloning purification, RNA analysis and purification, viral diagnostics, short tandem repeat analysis, population analysis, primer extension, pooling of genomes to determine allele frequency, and many other applications.

Early nucleic acid separations have been described by J. Thompson in review articles. The fundamental technology leading to modern DNA chromatography was first described by Guenther Bonn, Christian Huber, and Peter Oefner in 1993. They showed a new nonporous, alkylated polymer column that provided rapid, high-resolution separations of both double-stranded and single-stranded DNA and were performed usually in less than 10 min, and, in many cases, single base pair resolution was achieved. Figure 1 shows an example of a separation of double-stranded DNA.

Ion pairing, reverse phase chromatography is the basis for most DNA chromatography technology and applications. An alkylammonium salt is added to the eluent, and this forms neutral ion pairs when a DNA sample is introduced into the HPLC instrument. An eluent gradient of an acetonitrile solvent separates the DNA fragments with the smaller fragments coming off the column first and then larger fragments eluting off the column and traveling through the detector.

Bonn and coworkers showed that the DNA separations were performed generally according to the size of the fragment, just as they do in gel electrophoresis. For double-stranded DNA, the particular sequence does not contribute to the retention of the fragment. Figure 2, taken from their work, demonstrates this with a plot of retention time versus fragment size for a number of different fragments. Various plasmids were digested with a number of different enzymes so that a mixture of DNA fragments was generated. Since the sequences of the plasmids are known, the effect of DNA sequence on their elution time can be shown. In the plot, all of the retention times of the various fragments fall on a line drawn through the data. This

Fig. 2 The capacity factors of various plasmid digest fragments are plotted according to size. The fragments have different sequences, but are separated according to their size using a DNASep® column 50 × 4.6 mm. Eluent and Gradient: A: 0.1 M TEAA; B: 0.1 M TEAA, 25% acetonitrile, 0 to 100% B in 30 min., 1.0 mL/min flow rate, UV detection at 254 nm (data from Huber, C.G., Oefner, P.J., Bonn, G.K. (1993) Rapid analysis of biopolymers on modified non-porous polystryrene-divinylbenzene particles, *Chromatographia* **37**, 653–658.)

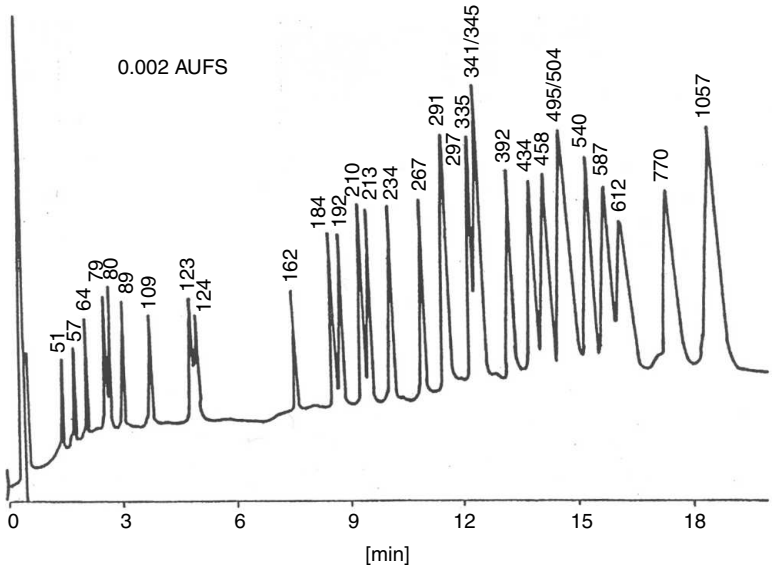

Fig. 1 High performance DNA chromatography separation of double-stranded DNA using a DNASep® column 50 × 4.6 mm. Sample was a mixture of Br322 HaeIII restriction digest and ΦX174 Hinc II restriction digest. Eluent and Gradient: A: 0.1 M TEAA; B: 0.1 M TEAA, 25% acetonitrile, 35 to 45% B in 2 min., 45 to 57% in 10 min., 57 to 61% in 4 min, 1.0 mL/min flow rate, UV detection at 254 nm, TEAA is triethylammonium acetate (Bonn, G., Huber, C., Oefner, P. (1996) *Nucleic Acid Separation on Alkylated Nonporous Polymer Beads*, U.S. Patent 5,585,236. with permission).

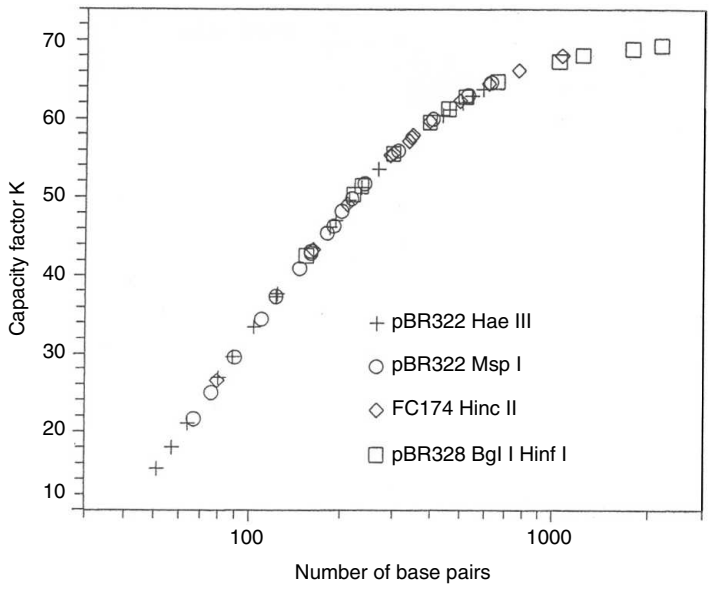

shows that the retention of DNA is dependent on fragment size, and is independent of fragment sequence. However, the selectivity of the separation of single-stranded DNA is based on both size and fragment sequence (i.e. some size reversals can occur in the separations).

A key development of modern DNA chromatography was performed by Gjerde, Haefele, and Togami, where they showed the detrimental effect of metal contamination and other contamination on the performance of the DNA separations. Without this development, reproducible and predictable separations of DNA could not have been performed and a commercial column could not have been developed. Furthermore, it was shown that a variety of polymer-based and silica-based columns could be used for DNA separations as long as they had good transport kinetics for the large nucleic acid biomolecules (i.e. the column packing should not trap the large biomolecules), and, most importantly, were free of metal contaminants or could be cleaned with an (chelating) additive in the eluent. Requirements of the column and system to be free of contamination are more critical for double-stranded DNA separation than for single-stranded DNA separations.

In 1996, Oefner and Underhill extended DNA chromatography with the invention of denaturing HPLC. By controlling the column temperature of DNA chromatography column, they demonstrated that DNA chromatography possessed unique properties, enabling the separation of double-stranded DNA based on its relative degree of helicity. Heteroduplex DNA has a lower melting point than homoduplex DNA. This technique is called *denaturing high performance liquid chromatography* (DHPLC). In short, they developed a method of DNA chromatography that is analogous to denaturing gradient gel electrophoresis (DGGE).

Many of the newest RNA and DNA applications of DNA chromatography have been performed by David Hornby and coworkers, and are described in Sect. 2 of this article.

In addition to these application developments, there have also been developments in separation media for DNA chromatography. Investigators have recently developed columns that are not made from packed beads (as in standard columns), but are rather made of a single polymer structure that extends the entire length of the column – thus giving them their common moniker of ''monolith columns.'' The polymer structure possesses so-called ''through-pores'' that allow sample eluent to pass through, which are analogous to the spaces between the beads in a standard column. For the separation of biopolymers, Horvath and coworkers applied this type of polymeric column for the separation of proteins, while Huber and coworkers have shown these types of columns to provide excellent separation of nucleic acids for mass spectrometric detection. These columns have also been referred to in the section on DHPLC.

1.2 General Principles

1.2.1 Overall System

This section discusses the principles of DNA chromatography. While instrumentation is important, the key to the separation process is the chemistry that occurs within the column (the stationary phase) and eluent (the mobile phase).

DNA chromatography employs the following:

1. An efficient column with as high a resolving power as possible.

2. An eluting solvent or eluent that provides reasonable separation of the mixture.
3. A column/eluent system that attains equilibrium quickly so that peak broadening due to slow chromatography kinetic interaction rates is eliminated or minimized.
4. Elution conditions such that retention times are in a convenient range – neither too short nor too long.

One major difference between chromatography and electrophoresis is the use of gradient elution in chromatography. The content of the fluid (eluent) that is pumped through the column can be changed in real time as the separation is proceeding. This is called a *gradient process*, whereby the ''strength'' or ''eluting power'' of the eluent is increased as the separation is developed. Small fragments are eluted first and then the organic solvent is increased and larger and larger fragments are eluted. The time required for the entire separation depends on the ''eluting program'' that is employed. A rapid increase in the stronger eluent will elute the fragments faster. However, if a rapid program is used, a separation with a lower resolution of peaks could result. Conversely, a slow gradient process will produce the highest resolving conditions and greatest separation of peaks. However, this carries the penalty of a longer separation time. If the DNA chromatographic system is well designed and a high-efficiency column is used, then rapid gradients will produce suitable and useful separations. Conversely, electrophoresis must rely on the conditions selected for the entire separation. The resolving conditions are not changed once the run is initiated; thus, whatever conditions were first selected must be used for the entire process.

Another advantage of DNA chromatography is the ability to detect the DNA fragment without fluorescence detection. Tags need not be used and the fragments may be detected directly at the subnanogram level by UV automatic detection. Of course, fluorescence detection could also be used provided fluorescent tags are added to the DNA in the PCR amplification. Alternatively, a fluorescent tag can be added as an intercalating dye. Use of this detection method decreases the amount of DNA that can be detected by a factor of 10 to 100 (or even 1000 in some reported cases).

Figure 3 shows a block diagram of the general components of a DNA chromatography instrument. The components are as follows: a supply of eluents or buffers (also called the *mobile phase*), an eluent degasser to remove dissolved oxygen, carbon dioxide and nitrogen from the fluid, a high pressure pump (with pressure indicator) to deliver the eluent or mobile phase, an autosampler, including syringe and sample valve, for introducing sample into the eluent stream and onto the column, a column (also called the *stationary phase*) to separate the sample mixture into the individual components, an oven to contain the column and control the temperature of the nucleic acids, a detector to measure the peaks or bands of the nucleic acid fragments as they elute from the column, an optional fragment collector to collect any particular fragment of interest, and a data system for collecting and organizing the chromatograms. A computer controls the instrument through software that is used to develop and implement analytical methods for each set of samples. The software guides the user to calibrate the instrument and to develop the appropriate and optimum methods, depending on the analysis

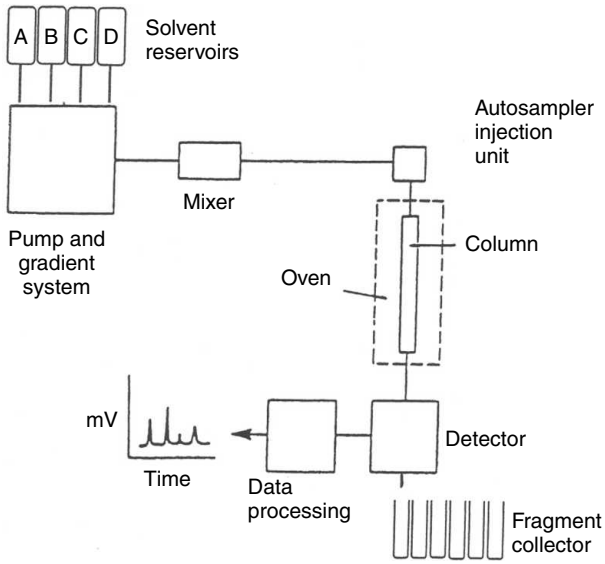

Fig. 3 Block diagram of a DNA Chromatograph.

being performed and whether fragments are to be collected.

Unlike electrophoresis gels that are used only once, the chromatographic column is used for several hundred or even thousands of injections before it is replaced. The eluent is pumped continuously through the column. Periodically, samples are injected and separated. A particular mix of eluent strength is used for each separation depending on the sample type (fragment sizes) and the desired separation.

The columns are packed with beads that provide the basis for the separations. Most column packings are beads approximately 2 µm in diameter, functionalized with a hydrophobic, neutral C18 alkyl group or they are functionalized with quaternary ammonium groups, which serve as the sites for an anion exchange process. A popular trademark name for this material is called DNASep® column and is supplied by Transgenomic, Inc., Omaha, NE. Another older type of column material is an anion exchanger available from a number of manufacturers, including Dionex, Inc. Sunnyvale, CA, and Tosoh Corporation of Japan. Although most of the recent work has been performed with neutral reverse phase materials, anion exchange is still used, especially for the separation of short, single-stranded DNA.

1.2.2 **Column Protection**

Column protection not only extends the useful life of the separation column, but proper protection of the separation column can also result in more reliable analytical results over the lifetime of the column. Dirty columns can show broad and, sometimes, even split peaks. The most common protection is the use of in-line filters located directly in front of the separation column. Material that would normally be trapped and would contaminate the separation column instead gets trapped by the filter. In-line filters are quite inexpensive and should

be changed frequently – at least every 2 to 3 weeks and sometimes much more often.

Another method to protect the system from metal contamination is to add small amounts (i.e. 0.1 mM) of tetrasodium EDTA to the mobile phase. This can be done without significant changes to the chromatography; however, this can affect removal of the solvent in nucleic acid material collected from the column to be used in further processing.

1.2.3 Use of the Column Oven and Temperature Modes of DNA Chromatography

The oven controls the temperature of the fluid entering the separation column. This includes not only the eluent but also the sample that is injected into the system. Temperature of the fluid can be thought of as an additional reagent used in the separation and analysis of nucleic acids. This is best described in the three modes of operation of analysis: nondenaturing mode, partially denaturing mode, and fully denaturing mode.

Nondenaturing mode The breaking of hydrogen bonds of double-stranded DNA through increasing the temperature is called *melting*. The temperature at which this occurs depends on the strength of the hydrogen bonding and the environment around the DNA. Higher salt and buffer content will raise the melting temperature. Also, DNA adsorbed onto a solid surface, such as column packing material, will require higher temperature to melt the DNA. Conversely, the presence of an organic solvent such as acetonitrile will lower the melting temperature. The effect is increased with increasing concentrations of the solvent. In the nondenaturing mode, high enough temperature is chosen to lower eluent viscosity (and therefore column back pressure), but not so high that denaturing occurs. The normal temperature of operation is 50 °C.

Partially denaturing mode The use of partially denaturing mode is discussed in the section on DHPLC. Mutations are detected through a heteroduplex detection process. Under this mode, differences in melting of double-stranded DNA are detected because increased melting decreases the retention time of the fragment. The temperature is chosen depending on the sequence and the melting of the fragment being analyzed. Typically, oven temperatures between 54 and 72 °C are used. The method has been called a *difference-detecting engine* because it detects the presence of a heteroduplex regardless of the sequence being studied.

Fully denaturing mode Single-stranded DNA and RNA may contain secondary structure due to complementary sequences within its own fragment. If portions of sequences are complementary, the fragments may fold back on themselves through the formation of intramolecular hydrogen bonds, giving several different possible structures for the same fragment. The presence of these secondary structures is uncertain and nonreproducible and will lead to peak broadening if they occur. Increasing the temperature can break up the hydrogen bonding and therefore reduce some or perhaps most of the secondary structure. An example of this behavior is the separation of an RNA ladder at 40 and 75 °C, where the chromatographic peaks of the RNA become sharper and more uniform with increasing oven temperature because of the reduction of RNA secondary structure.

1.2.4 Detection

One of the great strengths of DNA chromatography over capillary and slab gel electrophoresis is that UV detection can be used without any previous modification of the nucleic acid. No tagging is necessary for separation and purification of nucleic acids. Still, fluorescence has its strengths, and, for general R&D purposes, many researchers use UV and fluorescence detectors simultaneously. They are connected in series with UV detection first, followed by fluorescence detection. However, if only one detector were available for an instrument, the general UV detector would be the detector of choice.

Coupling to ESI-MS provides information about the size of the DNA fragment and allows a confident identification and characterization.

2 New Applications of DNA Chromatography

2.1 Analysis Using Enzymatic Site-specific Cleavage

Contemporary molecular biology has emerged through the integration of genetics, biochemistry, chemistry, and biophysics, and centers on the metabolism of nucleic acids. In experimental terms, the development of our understanding of nucleic acid synthesis, degradation, modification, and expression has relied heavily upon nucleic acid separation, isolation, and detection methods. By far, the most widely used method for nucleic acid separation is gel electrophoresis. However, gel electrophoresis presents problems of quantification and is difficult to use in a preparative mode.

One of the fundamental steps in the analysis and characterization of genomic DNA and in molecular cloning is the enzymatic, site-specific cleavage and detection of DNA using restriction endonucleases. Type II restriction endonucleases cleave DNA at specific sites that are usually palindromic and typically recognize between 4 and 8 bp. With careful choice of the eluent, DNA chromatography can be used to separate fragments generated from such reactions that are up to 1000 bp in length. An example of the use of DNA chromatography in the preparative separation of restriction fragments for molecular cloning has been described by Matin and Hornby. When the linear ''chromosome'' of bacteriophage ϕX174 is hydrolyzed to completion by HaeIII, a series of DNA fragments are produced ranging in size from 72 to 1353 bp. Separation of these fragments by DNA chromatography under nondenaturing conditions yields the chromatogram shown in Fig. 4.

Clearly, in view of the ease with which chromatograms can be analyzed quantitatively, DNA chromatography can be made in the analysis of the kinetic and chemical mechanisms of restriction enzymes and nucleases in general. This experimental approach has been widely used in the study of mechanistic diversity amongst restriction endonucleases, but has until now relied on electrophoretic separation and the use of tritiated plasmid DNA to provide accurate quantitative data; such experiments are greatly facilitated by DNA chromatography.

2.2 DNA Methylation Analysis

Following biological replication, DNA may become modified by methylation, extended by the action of telomerase, damaged by alkylation, interrupted by recombination, or mutated by erroneous

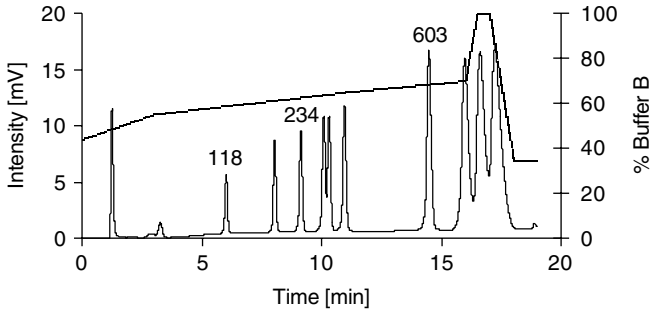

Fig. 4 Size-based separation of bacteriophage ϕX174 DNA following restriction digestion with HaeIII (the numbers above the peaks indicate fragment sizes in base pairs).

repair. This intrinsic plasticity of the genome contributes to the phenotype of a given cell or tissue and paves the way for evolutionary change. Therefore, there has been substantial interest shown in the molecular processes that lead to these and other DNA modifications. For example, the phenomenon of genomic imprinting and some aspects of developmental gene regulation are intimately associated with region-specific cytosine methylation.

Single nucleotide methods have recently been introduced in order to identify those specific cytosines that undergo methylation and demethylation *in vivo*. Such methods are generally based on the differential susceptibility of methylated and unmethylated cytosines to sodium bisulfite (Bis) mediated deamination. Following differential deamination, those bases that were originally methylated remain as Cs, and those that were unmethylated become Us. In the final stage of analysis, which typically involves PCR amplification, methylated C:G base pairs are retained in the PCR product, while unmethylated C:G base pairs are converted to T:A, and nucleotide sequence analysis provides a facile method of distinguishing the two.

Although deamination of cytosine proceeds at a significantly greater rate than deamination of the corresponding methylated form, the reproducibility of the method is often unsatisfactory and ''statistical'' (i.e. the same fragment must be analyzed more than once to establish a consensus). Still, with proper controls bisulfite sequencing has become the accepted approach to the robust analysis of the methylation status of a given genomic segment. DNA chromatography can provide a rapid means of evaluating the outcome of a deamination reaction. Thus, the deamination of a specific cytosine in the oligodeoxynucleotide homoduplex containing the sequence GAATTC (an *Eco*RI restriction site) can be assessed by the outcome of an *Eco*RI restriction endonuclease reaction as a function of the rate of a bisulfite deamination reaction. If bisulfite deamination is 100% successful, there will be no cleavage of the site since the sequence GAATTU is not a substrate for the enzyme; incomplete deamination is manifested by the appearance of two short duplices. Figure 5 shows the successful outcome of a bisulfite-mediated deamination reaction together with those species expected if deamination is incomplete. This quality control experiment, which is much easier to quantify by chromatography than electrophoresis, can lead

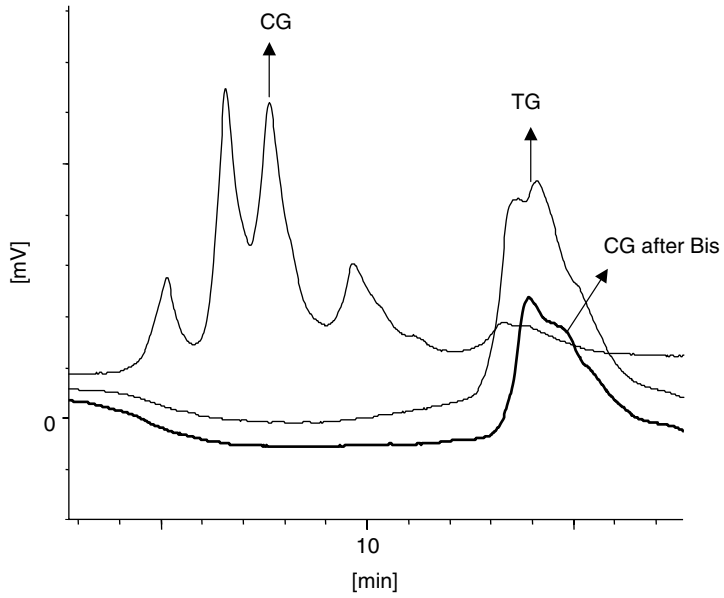

Fig. 5 Indirect monitoring of bisulfite (Bis)-mediated deamination of cytosine containing DNA duplices. An oligodeoxynucleotide duplex containing a unique, asymmetrically positioned *Eco*RI restriction site (GAATTC), was digested with an excess of *Eco*RI before (labeled CG) and after (CG after Bis) bisulfite deamination. As a control, a duplex, in which the *Eco*RI site was mutated to GAATTT (labeled TG) to mimic deamination, was also subjected to denaturing DNA chromatography. By linking restriction endonuclease susceptibility to deamination, this set of DNA duplices can be used to evaluate the outcome of any deamination reaction in a quality control manner. The deaminated strand is clearly distinguished from the cleaved species.

to a significant improvement in the reproducibility of bisulfite reactions when carried out in parallel with deamination reactions on PCR products. This can be important given that the variation in genomic DNA preparations and in the quality of the bisulfite reagents militate against reproducibility. DNA chromatography in conjunction with bisulfite deamination is well suited to the investigation of DNA methylation. Indeed, recent applications of DNA chromatography for the analysis of genomic DNA methylation have been reported that offer an alternative to conventional nucleotide sequencing.

2.3 Phosphorylation Analysis

DNA chromatography represents a generic platform for many aspects of nucleic acid enzymology as exemplified below by assays polynucleotide kinase. However, this approach is not confined to this reaction. Indeed, the ability to perform a variety of nonradioactive assays with throughput times of 10 min per sample in conjunction with in-line data analysis software represents a new direction for DNA chromatography. For example, polynucleotide kinase catalyzes

the transfer of a phosphate group from ATP to the 5′-OH of DNA, RNA, and nucleoside 3′-monophosphates. The enzymatic phosphorylation of 3′ hydroxyl groups of synthetic oligodeoxynucleotides has widespread application in experimental molecular biology. For example, the labeling of oligodeoxynucleotides as probes for identification of target sequences by hybridization is a key technique in molecular cloning. The addition of ^{32}P-labeled phosphate groups to oligodeoxynucleotide sequences using polynucleotide kinase is a common method for creating these labeled probes. Assessment of the proportion of probe that has been labeled and separation of the labeled probe from the unlabeled substrate duplex (or single strand) is normally not undertaken owing to the difficulty of carrying out such procedures.

This subtle ionic difference between phosphorylated and unphosphorylated DNA is readily resolved by DNA chromatography when the nucleic acid fragment is less than 50 bases in length. This can be demonstrated by separating the product from the substrate in a reaction containing an unphosphorylated oligodeoxynucleotide and polynucleotide kinase. Figure 6 shows the effects of phosphorylation of a single-stranded oligodeoxynucleotide upon retention time following DNA chromatography. Phosphorylation of the oligodeoxynucleotide reduces the retention time of the modified DNA, owing to the addition of the polar phosphate group, which diminishes the net hydrophobicity of the DNA. These data are readily corroborated by mass spectrometry. This particular application of DNA chromatography demonstrates not only the utility in molecular biology but also presents, for the first time, a rapid assay method for exploring the biochemical properties of polynucleotide kinases.

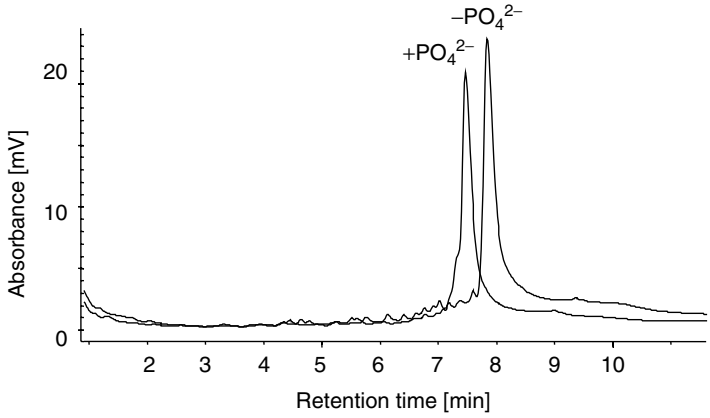

Fig. 6 The use of DNA chromatography in the resolution of differentially phosphorylated oligodeoxynucleotides under denaturing conditions. The difference in polarity between the two species is clearly sufficient to resolve the strands, which may be up to 50 to 100 nucleotides in length. Confirmation of the products was obtained by mass spectrometry, which is a powerful complementary technique to DNA chromatography since the eluted material is ideal for mass spectrometry.

2.4 Footprinting

The regulation of expression and the introduction of structural modifications to the genome rely on proteins that bind to specific DNA sequences or structures. The understanding of how such proteins recognize their binding sites in the midst of a plethora of similar sequences in the genome is an important step to understand such processes at the molecular level. Over 30 years ago, Galas and Schmitz introduced an elegant method called *footprinting* to determine the contacts between a specific DNA duplex and a protein.

Standard footprinting reactions involve the binding of a protein to radioactively labeled DNA, containing the sequence that the protein recognizes. This complex is then digested either enzymatically using DNase I or chemically using hydroxyl radicals. The regions of the DNA molecule covered by the bound protein are protected from digestion while the rest of the DNA backbone undergoes cleavage. The products of the reaction are then separated using electrophoresis; the extent of digestion can then be quantified by further analysis of the gel. A blank region on the autoradiograph is called the *footprint* and this corresponds to the site of the protein binding to the DNA.

Modifications to the standard footprinting reaction that allow the reaction products to be analyzed by DNA chromatography include the use of fluorescently labeled DNA. One of the strands of the duplex contains a 5′-fluorescent group introduced during the synthesis of the DNA. This facilitates the analysis of the cleavage products with the aid of a fluorescence detector at the appropriate wavelength(s). Analysis of the footprinting products is rapid with run-times of approximately 30 min for each sample. Direct quantification of the cleavage products is performed using peak evaluation software. The analysis of a protein–DNA interaction using hydroxyl radical footprinting is exemplified here by the interaction between the RuvA component of the bacterial resolvasome and a synthetic four-stranded Holliday junction.

Before discussing footprinting data, it is necessary to consider the choice of ion pair reagent and the methodology associated with ''phasing'' the footprint; that is, relating the chromatogram obtained in the presence of the protein to the nucleotide sequence of the DNA duplex. The use of tetrabutylammonium bromide (as the ion-pairing reagent) with DNA chromatography is essential for the (almost or near) size-dependent separation of fluorescently labeled DNA. This regime removes the influence of the hydrophobic fluorescent group and any residual sequence-specific effects. The sequencing reactions performed involve an express protocol for the generation of a ''GA ladder''. This method does not provide complete sequence information; instead, it produces cleavage at every G and A residue within the oligodeoxynucleotide strand. However, the Maxam–Gilbert sequencing protocol for complete sequence identification may also be performed, as the chemistries are very similar. Simultaneous nucleotide sequencing is required to allow complete identification and phasing of all the peaks in the footprinting reaction. The footprinting reaction can generate over 40 chromatographic peaks, and it is important to correctly identify each peak (which can often be difficult in the presence of an injection and salt peaks at the start of a chromatogram). Overlaying the GA sequence ladder allows complete characterization of the footprinting reaction once

the sequence of the GA ladder has been determined. Some small peaks arise in the sequencing reaction due to small amounts of cleavage at TA residues; however, these anomalous products can be minimized by optimizing the reaction conditions.

The Holliday junction and Holliday junction-RuvA complexes that had been subjected to hydroxyl radical cleavage were analyzed under denaturing conditions at 75 °C using DNA chromatography (Fig. 7). The chromatogram of the hydroxyl radical

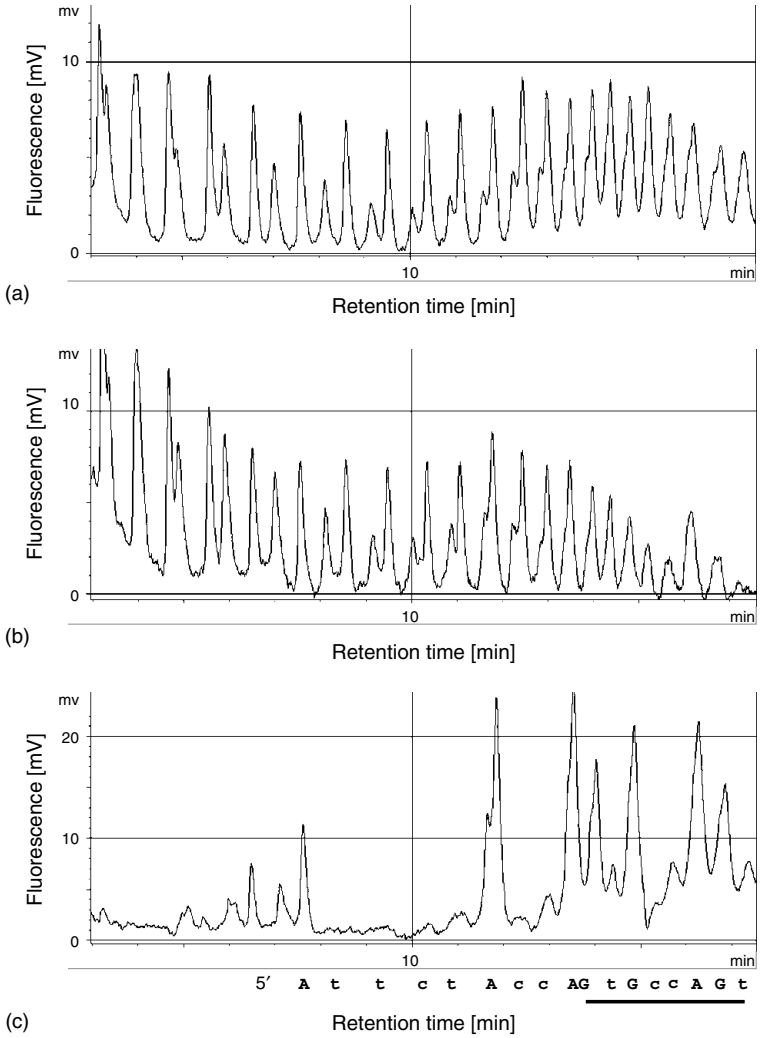

Fig. 7 The comparative analysis of a DNA four-way junction in (a) the absence of the bacterial recombination protein RuvA, (b) in the presence of the protein, and (c) a corresponding Maxam–Gilbert G + A reaction. This experiment shows that hydroxyl radical cleavage is inhibited by the presence of the RuvA protein (solid line underneath chromatogram c, which is an indirect measure of the specific bases that are in contact with the protein).

cleavage products from the Holliday junction in the presence of RuvA compares sharply with the cleavage products generated in the absence of the protein (compare Figs. 7a and 7b). Using peak analysis software, the direct quantification of the cleavage products can be achieved by determining the areas under the peaks in each chromatogram. This technique also facilitates the identification of the individual peaks by alignment with fragments from a GA sequencing ladder (see Fig. 7c). Previous DNase I footprinting experiments have shown that RuvA binds to the Holliday junction, producing a symmetrical footprint, extending approximately 13 bases on either side of the crossover point. Hydroxyl radical footprinting analysis of the RuvA-Holliday junction complex using this novel fluorescent-based analysis determined a more precise footprint, covering approximately 9 to 10 bases either side of the crossover point. The results from the hydroxyl radical footprinting experiment is in excellent agreement with crystal structures of the RuvA-Holliday junction, which show a tetrameric RuvA extending over 8 bases of the crossover point of the Holliday junction.

3 Denaturing High Performance Liquid Chromatography (DHPLC)

Denaturing HPLC, or what is often referred to as DHPLC, is the single most published-upon application of DNA chromatography. Its growth in popularity is superbly documented within reviews dedicated to the topic of DHPLC as a whole. DHPLC has been used for the analysis of hundreds, if not thousands, of different genes within the human and other genomes for their mutations.

The reason DHPLC has become so popular is because of the questions it answers. In short, DHPLC is capable of indicating whether a genetic sequence up to 1 kb in length carries any sequence alteration relative to some reference sequence. There are a number of reasons for gaining this type of information, such as the discovery of anonymous common sequence variants for performing genetic association studies, discovery of potential common functional variants within polygenes, or screening for detection of disease-causing mutations within inherited disorders. As demonstrated by the review articles cited above, all of these areas have contributed to the substantial growth in DHPLC's popularity and general acceptance.

This section on DHPLC begins by describing the basis of the technique's function and operation. This is followed by more detailed descriptions of the factors that must be attended to for successful DHPLC analyses (such as DNA melting behaviors and optimization of PCR conditions). A review is given of the milestones within the development of DHPLC, as well as introducing recent developments and special techniques within DHPLC.

3.1 The Basis of DHPLC

DHPLC is based on the detection of heteroduplex DNA in the presence of homoduplex DNA. A pair of primers is designed to generate a PCR product that is typically less than 1 kb in length, which spans the sequence region of interest. Individuals who are, for instance, heterozygous for a single nucleotide polymorphism (SNP) have a 1 : 1 ratio of wild-type and mutant DNA. Heating the PCR product to 95 °C and cooling slowly hybridizes the material

to form a mixture of heteroduplex and homoduplex species (Fig. 8). In cases where the individual possesses a mutation in both alleles, (a homozygous mutation), known wild-type PCR product is mixed with the sample PCR material and then the mixture is hybridized to form the heteroduplex and homoduplex species.

The heteroduplex contains a physical "bubble" of the two strands at the mutation site caused by a disruption in the hydrogen bonding at the site of the mismatch. The fundamental process governing the separation of heteroduplexes from homoduplexes in DHPLC is an increase in a heteroduplex fragment's overall single-strandedness or an increase in polarity of the fragment, resulting in reduced adsorption on the separation medium's surface. A larger proportion of the hydrophilic "core" of the DNA double helix is available for hydrogen bonding to the aqueous component of the eluent. The heteroduplex more easily desorbs from the column bead surface and is solvated by the eluent (as compared to its less single-stranded, homoduplex counterpart). At elevated temperature, this mismatch bubble becomes enlarged relative to the corresponding homoduplex. If the temperature is increased too much, all duplex species will completely melt into single strands and will not be separated from each other. Under ideal conditions (choice of primers, column temperature, fragment characteristics, etc.), four peaks will be detected – two each for each duplex (Fig. 9). More likely, only two or three peaks (either partially or fully resolved) will be detected, thus indicating the presence of a mutation.

3.2 DHPLC and Its Practice

3.2.1 DNA Melting Fundamentals

Successful practice of DHPLC lies in understanding and exploiting of DNA melting processes. DNA melting is a cooperative process. An often-invoked analogy for the description of DNA denaturation is a line of interconnected, buoyant pontoons floating on the surface of a body of water. If one of the pontoons is forced below the water's surface, then the others will also be forced below the surface as a result of their being interconnected. In other words, the buoyant bodies are "cooperatively" floating or submerged. In most cases, DNA denaturation occurs in much the same way. If the hydrogen bonding of two base pairs in the DNA double helix is disrupted as the result of any particular process (e.g. the presence of heat, chemical denaturants, mismatched base pairs, or combinations of any of these forces), the bases surrounding them are correspondingly disrupted

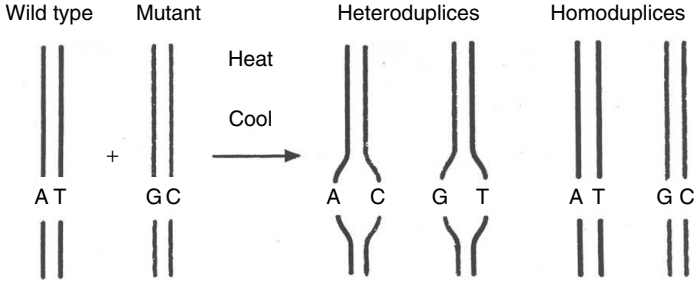

Fig. 8 Two heteroduplex species and two homoduplex species are formed when a mutation is present.

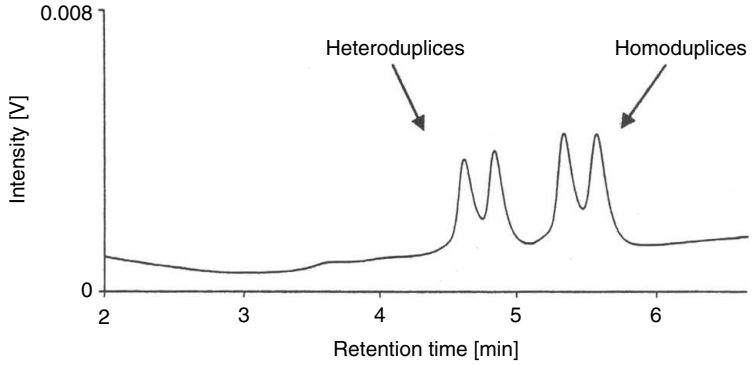

Fig. 9 Under ideal conditions, DHPLC will produce a four-peak pattern: two for each heteroduplex complex and two for each homoduplex. Usually, heteroduplices will not be completely resolved, and only a two- or three-peak pattern will be observed.

and the segment of DNA denatures as a whole. In other words, the DNA denatures "cooperatively." The segment in which cooperative melting occurs is referred to as a *domain* and is typically anywhere from 50 to 300 bases in length. Domains that are rich in G – C nucleotide hydrogen bonding melt at higher temperatures than domains that are rich in A – T hydrogen bonding. The detailed processes that govern the formation of domains, as well as the chemical processes involved in their melting, have been described in detail elsewhere.

As discussed, a normal (homoduplex) fragment is composed of domains that melt cooperatively at different temperatures. The mismatch within the heteroduplex will also act in a domain manner by depressing the melting temperature of the entire domain in which it resides and not just the sequence in direct contact with the mismatch site. Under the correct analytical separation conditions, the mismatch-containing domain within the heteroduplex will be considerably more denatured than its homoduplex counterpart. As stated above, this increase in single-strandedness for the heteroduplex means that its ability to remain on the surface of the resin is significantly reduced relative to the homoduplex. In other words, the destabilizing effect of the base mismatch is effectively exaggerated or "amplified" as a result of cooperative domain melting behavior. Collectively, this gives rise to separation patterns (chromatograms) that are largely more complex (either have more peaks or at least has a much broader peak) in cases where a mutation is present, compared to when a mutation is not present.

It is possible to select the DHPLC column oven temperatures without considering the effects of cooperative domain melting behaviors. If a homoduplex fragment peak's chromatographic retention time is plotted as a function of the column oven temperature, one will often observe a well-defined sigmoidal plot. The fragment may have more than one domain due to the different slopes of the inflection of the melt curve. However, a plot of this type usually shows a single curve extending over the melt region. The user may choose a run temperature indicated by the midpoint or multiple temperatures,

depending on the length and shape of the curve.

DNA melting predictions DHPLC temperatures can be selected by modeling the fragment's melting behavior in advance. The ability to predict a fragment's melting behavior *ab initio* has more than one benefit associated with it. For one, it is possible to predict a single set of analytical conditions for mutation detection. In a highly ambitious study that involved DHPLC mutation analysis of many hundreds of different fragment sequences, investigators determined that a single DHPLC analysis temperature provided 87% mutation detection sensitivity, with no attention being given to multidomain melting behaviors or PCR product design whatsoever.

The second benefit associated with melting prediction is that it provides the means necessary for obtaining virtually 100% mutation detection sensitivity. As noted above, a multidomain fragment can result in less reliable determination of temperature, since more than one melting domain can result in a bias to the predicted "optimum temperature." However, with *a priori* knowledge of more than one melting domain, it is possible to avoid improper selection of the analysis temperature. Shown in Fig. 10 are two plots for a particular sequence 300 bp long. The first plot shows "Helical fraction (%)" as a function of "Temperature." The second plot shows the melting "Temperature" as a function of base position, and is well known to practitioners of DGGE as a "melt map."

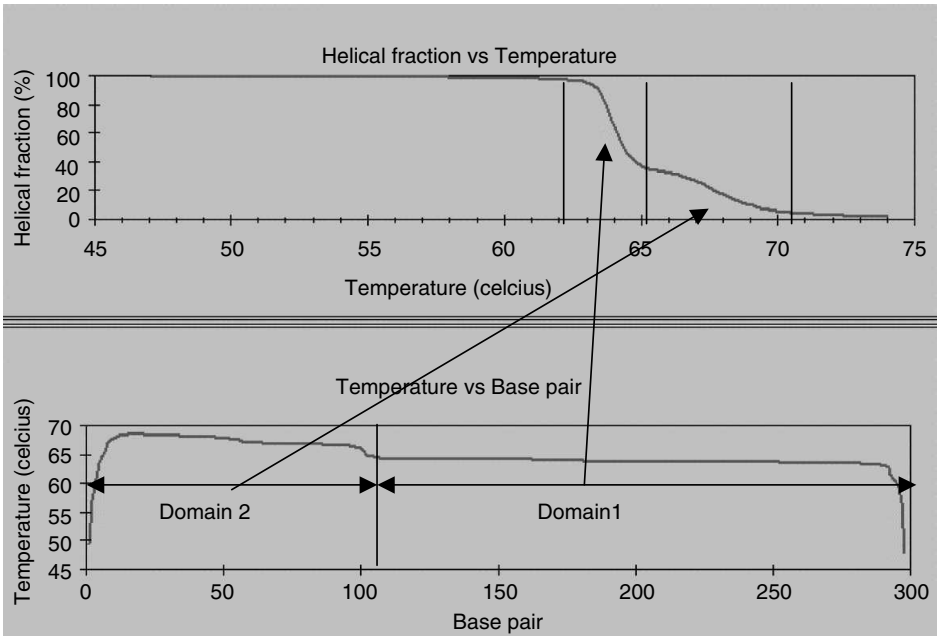

Fig. 10 Correlation of predicted thermal titration data (shown at the top of figure) and melt map features (shown at the bottom of the figure). Predictions performed with WAVEMaker® software, Transgenomic, Omaha, NE.

These algorithms have been optimized to predict melting behavior in solution states different from those commonly applied in DHPLC. For the purposes of DHPLC, these predictive algorithms must be adapted to reflect the presence of acetonitrile (an organic solvent) and triethylammonium acetate (a salt and ion-pairing reagent) in the separation environment (a nonpolar surface), since both of these components have significant effects on fragment melting behavior. An organic solvent will decrease the fragment melting temperature, a salt will increase temperature, and in the presence of a ion-pairing reagent, a nonpolar surface will increase the temperature. The extents to which these components influence fragment melting have been described in detail. DHPLC algorithms of this nature are available commercially through WAVEMaker® software (Transgenomic, Inc.) or via the Internet (http://www.insertion.stanford.edu/melt.html). Once these operations are performed, it is possible to accurately predict the analytical conditions required for complete DHPLC analyses: the analytical separation gradients are generated, and the analytical temperature is predicted in the manner described above. This general predictive approach to DHPLC analyses has been validated on numerous occasions. In summary, it has been shown that this approach can detect anywhere from 87% of mutations (single temperature selection with no fragment or PCR optimization whatsoever) to 100% of mutations (one or more temperatures selected with fragment optimization).

PCR optimization Temperature prediction alone will not always provide conditions that are fully optimized for the detection of every possible mutation. This is particularly the case when attempting to detect mutations located in high-melting domains within a fragment. This situation is addressed through PCR primer optimization. In the context of DHPLC, what is meant by PCR primer optimization is the selection of primer sequences that give rise to fragments whose melting characteristics are propitious with respect to the detection of mutations within a particular sequence. Of course, any primers that are optimized for DHPLC must also be appropriate for PCR amplification.

These points are well illustrated in the example shown in Fig. 11. These are melt maps for the same mutation, but with different primers selected. It is clear from map #1 that the mutation resides in a low-melting domain, and that the vast majority of the fragment (roughly 75%) is unmelted at the temperature that corresponds to the domain that possesses the mutation. In map #2, the mutation also resides in a low-melting domain, but a smaller proportion of the fragment (roughly 40%) is unmelted at the temperature that corresponds to the domain that possesses the mutation. In map #3, this proportion is reduced even further (roughly 15%). Important to note here is that the fragment size is identical in each case, and all that varies is the proportion of unmelted fragment at the mutation domain's melting temperature.

Figure 12 shows the consequence of these differences. The separation shown in Fig. 12(a) is not only sufficient for baseline resolution of the heteroduplices from the homoduplices but also for the separation of these duplices from one another. In Fig. 12(b), the resolution is clearly diminished, but still allows for highly reliable detection of the mutation. In Fig. 12(c), the heteroduplex is barely resolved from the homoduplex. There still is enough resolution for detection of the mutation, especially when using

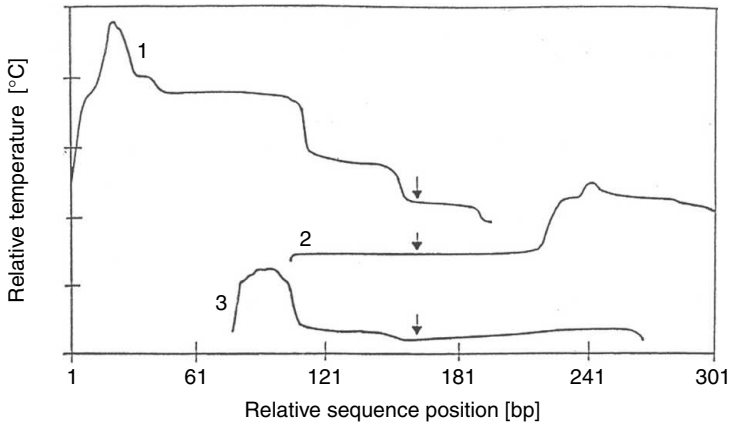

Fig. 11 Melt maps for the same p53 mutation with different primer locations selected relative to the mutation location (Gjerde, D.T., Taylor, P.D., Haefele, R.M. (2001) *Mutation Detection Method*, U.S. Patent 6,287,822 with permission).

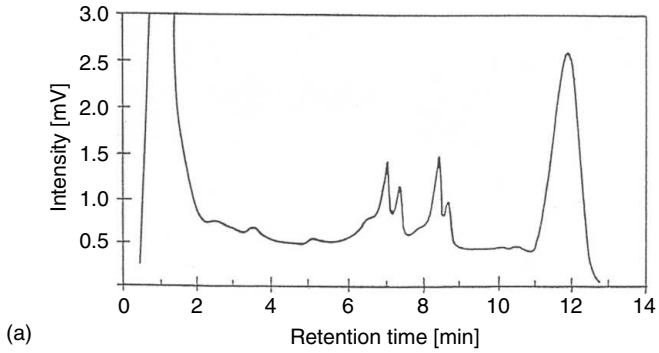

Fig. 12 (a) DHPLC chromatogram of fragment 1 of Fig. 4.5. (Gjerde, D.T., Taylor, P.D., Haefele, R.M. (2001) *Mutation Detection Method*, U.S. Patent 6,287,822 with permission). (b) DHPLC chromatogram of fragment 2 of Fig. 4.5. (from Gjerde, D.T., Taylor, P.D., Haefele, R.M. (2001) *Mutation Detection Method*, U.S. Patent 6,287,822 with permission). (c) DHPLC chromatogram of fragment 3 of Fig. 4.5. (from Gjerde, D.T., Taylor, P.D., Haefele, R.M. (2001) *Mutation Detection Method*, U.S. Patent 6,287,822 with permission).

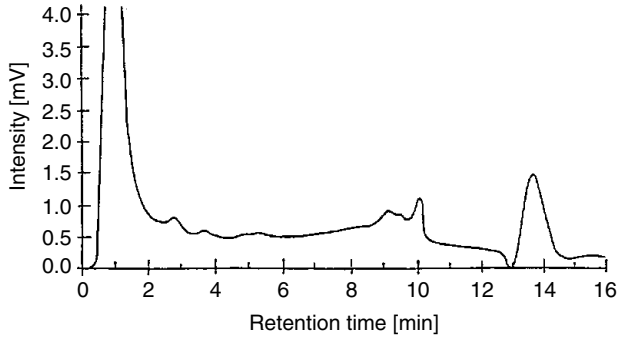
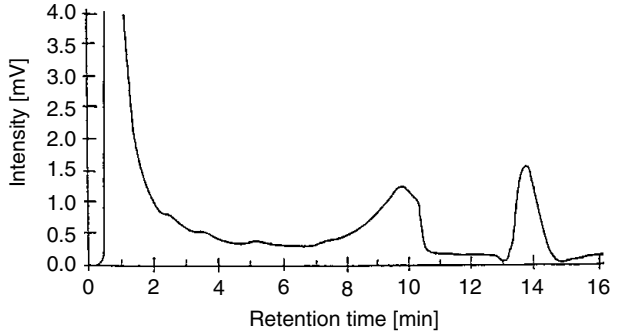
computer analysis, the detection is clearly more difficult.

In all three cases, the mutation is situated in a low-melting domain, which is why it is successfully detected in all three cases. However, our degree of analytical confidence is always greatest when the resolution for any given mutation is at its maximum. Therefore, maximization of detection confidence is achieved through



(b)



(c)

Fig. 12 (*Continued*)

proper primer optimization strategies that situate a sequence region for scanning in a low-melting domain with a high proportion of unmelted sequence adjacent to it, which is demonstrated here and elsewhere. The needs for the level of confidence must always be balanced against the detection productivity of the procedure. In other words, maintaining the absolute highest level of confidence at all times may necessitate analyzing numerous overlapping fragments for the presence of mutations, whereas fewer fragments can be scanned when the confidence level need not be at the absolute highest levels.

Even in cases where the confidence level can be relaxed, there are still circumstances where primer optimization does not yield conditions that allow reliable mutation detection. This is frequently the case when the region being scanned is in a high-melting domain, and no amount of primer optimization can render this domain more amenable to mutation detection (or, the scanned region is in a high-melting domain, and it is not possible to move the primer locations). A common means of overcoming this situation is the addition of a nontemplate GC-clamp to one of the primers used for amplification, which has been shown to work successfully in DHPLC. By doing so, one creates an additional high-melting domain adjacent to the region being analyzed for mutations. This general approach has been applied for over a decade in the context of DGGE, and is largely compulsory for the successful application of that technique.

However, in DHPLC, GC-clamps need only be applied in extreme circumstances such as those described above.

The detection of mutations by DHPLC requires the chromatographic separation of heteroduplices from homoduplices. The mutant sequence present in the template is carried through the PCR amplification process, the heteroduplices are subsequently formed through standard hybridization protocols, and the separation is commenced. While this is a generally straightforward procedure, one must always be on guard for the potential introduction of confounding artifacts brought about by the analytical procedure itself. One part of the DHPLC analytical technique where artifacts may be introduced is within the PCR process itself. PCR-induced mutations or amplification errors of sample can make detection of the sample mutations difficult or even impossible.

Differences in PCR fidelity, and how they present themselves in the DHPLC signal profiles, are shown in Fig. 13. For a given set of amplification conditions with a homozygous template, it is clear that the nonproofreading AmpliTaq® polymerase results in a significantly higher relative amount of background heteroduplices, whereas the proofreading *Pfu*® and *Pfu*Turbo® provide significantly reduced levels of this background. It is clear from these examples that the AmpliTaq®-derived signal could lead to misclassification of the sample being analyzed, whereas this is less likely for the higher fidelity results. Properly optimized amplifications can minimize the risk of misclassification with nonproofreading enzymes, while proofreading enzymes will always minimize the risk posed by the presence of background heteroduplices. The need for the lowest possible levels of background heteroduplices is most pronounced when attempting to detect mutant sequences at concentrations significantly lower than the 50% found in germline mutation detection situations.

3.2.5 **Other DHPLC Recommendations**

There is a strong need within DHPLC to have a system that is substantially free of any extraneous metal contamination. Any free transition metals in the

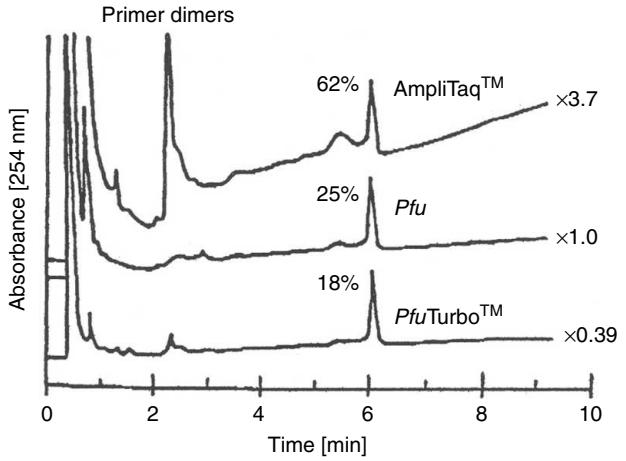


Fig. 13 Background heteroduplex signals generated as a result of PCR infidelities. The background signal is reduced upon application of a high-fidelity PCR polymerase.

system (such as iron) can compromise the analysis by interfering with efficient and precise interaction of the DNA fragment with the column material. While this has been observed for nondenaturing, size-based separation of DNA fragments with DNA chromatography, it is even more pronounced within DHPLC. Straightforward procedures are available for ensuring that metal contamination is eliminated, along with addressing other frequently asked questions (FAQs) regarding successful performance of DHPLC analyses.

3.3 Review of DHPLC Development

The first peer-reviewed publications that made use of DHPLC were in 1996. While these reports did not provide any significant information regarding DHPLC operation or optimization of its conditions, the power of the technique was clearly demonstrated by the speed and ease by which the analyses were performed for the PCR products generated.

The lack of detail regarding DHPLC was addressed in a number of publications in late 1996 and 1997. One paper dealt with the issue of DHPLC technique validation, while another paper mentions the critical issues surrounding fragment melting and their effects on heteroduplex retention by minimizing the stabilizing effects of G–C-rich regions.

With these beginnings for DHPLC, 1998 was a watershed year for the development of the technique as a whole. There was continued characterization of the technique through validation studies. In addition, there begins to be a much more detailed treatment of fragment melting behaviors with the publication and description of an internet-accessible algorithm that allows for prediction of DHPLC analysis temperature.

This work on elucidating the role of the various DHPLC analytical conditions continued in 1999. One paper gave a detailed description of melting processes and temperature predictions, and the principles behind this approach were applied to the analysis of *BRCA1* and *BRCA2* genes. Other publications in this same year made important empirical observations on the relationship between overall fragment melting patterns and the ability to detect mutations within DHPLC.

This enhanced understanding of DHPLC fundamentals and phenomena has led to the general acceptance of the technique, which is exemplified by the many publications that apply DHPLC as a matter of course to the analysis of many genes in many different contexts. This general degree of acceptance within the peer-reviewed literature began in 1999 and has continued to the present day. It is beyond the scope of this chapter to provide a complete listing of these publications.

The last two years have seen the extension of DHPLC's capabilities in new directions. One area is that of determining minority allele populations, which is relevant in various contexts (such as in detection of mutations within cancer cells present in a normal sequence ''background''). The optimization of DHPLC conditions for this type of analysis has been described recently, as well as using DHPLC for the purification, collection, and subsequent amplification of mutant sequence that cannot even be detected within standard schemes.

There have also been developments in the nature of the chromatographic

separation media. The use of monolithic capillary column materials (as opposed to packed particles) has shown to be effective at improving separation performance and miniaturizing analyses. Furthermore, this DHPLC format has been used for performing multiplexed/''capillary array'' separations, as well as being an effective separation means for interfacing to mass spectrometry. Developments within monolithic capillary columns for DHPLC have also been reviewed recently.

4 RNA Chromatography

4.1 RNA Structure

RNA molecules are central to the expression of genetic information in all living organisms. The product of transcription, messenger RNA (mRNA), carries the genetic instructions for decoding genetic information to the ribosome where protein synthesis takes place. In addition to these classical roles in cell biology, RNA is emerging as a key regulator of gene expression and has been shown to be capable of catalyzing a range of chemical reactions both *in vivo* and *in vitro*.

In contrast to double helical DNA, RNA molecules are much more structurally diverse. X-ray crystallography and multidimensional NMR have revealed the globular nature of a number of small biological RNA species, and it is likely that most mRNA molecules are even more complex in structure.

Our relatively slow accumulation of biochemical knowledge of RNA is largely a consequence of the inadequate methodologies available for its isolation, stabilization, purification, and characterization relative to RNA's biological partner, DNA. Indeed, while chemical synthesis of 100-mer oligodeoxynucleotides is routine, the synthesis of 30-mer oligoribonucleotides is still something of a synthetic challenge.

Our knowledge of RNA structure and function is largely extrapolated from structure and function studies on transfer RNA. However, with the development of high-yield enzymatic methods for the synthesis of RNA through the combination of gene cloning and *in vitro* transcription, the ability to carry out more rigorous biochemical and biophysical investigations of RNA is now becoming possible, and the need for both analytical and preparative chromatographic methods for RNA analysis are pressing.

One important aspect of translating human genomics into human physiology will involve the global analysis of whole cell populations of mRNA in disease and health, and the modulation of these populations during both natural physiological transitions and in response to drug administration. This aspect of RNA population biology is largely being addressed by microarraying technology and to a lesser degree by various RTPCR (reverse transcriptase polymerase chain reaction) approaches, including differential message display and serial analysis of gene expression. These forms of analysis of cellular transcriptomes typically produce high volumes of data and treat all RNAs as equivalent molecular species (similar in principle to two-dimensional SDSPAGE of proteins in proteome biology). The majority of DNA-DNA hybridization experiments can be considered as uniform Watson-Crick duplexes. The relationship between the function and structure of RNA lies somewhere between DNA and proteins. Therefore, hybridization-dependent

transcriptome approaches provide only a preliminary, and therefore limited, insight into the population biology of RNA at the cellular and tissue levels.

Here we present an overview of progress in adapting methods originally developed for the chromatography of DNA for the separation, stabilization, and analysis of RNA; this will be referred to as RNA chromatography. In the absence of an all embracing physical explanation for the separation of RNA species by RNA chromatography, we shall cautiously assume that the mechanism of separation is very similar under most conditions to that observed for DNA, but we shall add the caveat that there may well be different physical principles responsible for similar experimental outcomes.

RNA is a polymer of nucleotide units, which comprise of mainly pyrimidine (cytosine and uracil) and purine (adenine and guanine) bases, the sugar D-ribose and phosphoric acid. The nucleotides in RNA, as in DNA, are combined through phosphodiester linkages between the 5′ hydroxyl of one sugar and the 3′ hydroxyl of another. These polymer chains are not typically found as paired duplexes, but rather as complex forms that comprise paired segments and loops, which are often stabilized by metal ions. The most familiar structural element in an RNA molecule is probably the stem loop, in which a noncomplementary segment separates two complementary stretches of nucleotides. The resulting structure that often folds is a Watson–Crick-like duplex (the stem) closed off by an unpaired segment (the loop). Such stem loop modules are used routinely to display predicted secondary structures of complex RNA molecules: perhaps the most famous of which is the classical cloverleaf structure of tRNAs.

The conformation of the duplex segments (stems) in RNA is confined to the A form, owing to the steric consequences of the presence of a 2′ hydroxyl group on ribose ring (DNA, which is predominantly a B-form duplex *in vivo*, has a hydrogen atom at this position) and differences in sugar pucker. As an added structural consequence of the presence of the 2′ hydroxyl group, RNA can participate in an extended repertoire of intra- and intermolecular hydrogen bonding interactions.

One structural element that demonstrates the clear difference between RNA and DNA is the RNA pseudo knot, in which an antiparallel complementary duplex arises when the complementary sequences are separated by a sufficient length of chain. The structure takes the form of a handwritten letter, $\mathcal{L}$, the upper and lower complementary strands being linked by a pair of 3′ and 5′ loops.

This structural diversity, characteristic of biological RNA, therefore has significant consequences for the physical properties of these molecules when attempting to rationalize the chromatographic behavior of RNA. Chromatographic separation of RNA, using the same protocols as used in DNA chromatography will therefore be a function of parameters that include molecular weight (chain length), surface chemistry, and localized single- and double-stranded character. It is therefore likely that unless a given population of RNA molecules is completely free from secondary and tertiary interactions, by thorough thermal denaturation, for example, they will behave anomalously during chromatography compared to duplex DNA. These issues are addressed below after considering some practical aspects of RNA extraction and stabilization.

4.2 Biological Extraction of RNA

RNA is typically extracted from cells under strongly denaturing conditions since cells (and hands) contain ribonuclease enzymes, all of which will tend to disturb the original population of RNA species isolated from the cell after an unavoidable delay. All ribonucleases have a pair of histidine side chains in the active site that drive catalytic hydrolysis. These enzymes generally catalyze hydrolysis of the phosphodiester linkage by deploying suitably ionized histidine residues. Two types of strategies are generally used to overcome the deleterious effects of RNases during RNA preparation: addition of general protein denaturants such as urea and guanidine hydrochloride, or by addition of irreversible chemical modification (specific for ionized histidine side chains) agents such as diethyl pyrocarbonate. The key to the successful isolation of high quality RNA in good yield, however, remains largely a function of experimental experience.

When RNA from cell extraction is electrophoresed in agarose, the most abundant species are the two major rRNAs that are referred to as 16S and 23S in *Escherichia coli* (corresponding to 1542 and 2904 nucleotides, respectively) or 18S and 28S in most eukaryotes (corresponding to 1874 and 4718 nucleotides, respectively). The other major RNA molecules include a species-specific tRNA population comprising around 100 molecular species of 60 to 90 nucleotides in length, a 5S (120 nucleotides) rRNA species (5.8S, 158 nucleotides in mammals) and a small number of spliceosomal RNAs. In contrast, the population of mRNA molecules (the cellular transcriptome) is extremely diverse, ranging from several hundred to tens of thousands of nucleotides in length. Moreover, given that there appears to be around 40 000 separate genes in the human genome, with the potential for expression of a similar number of mRNAs in any given cell, the population of cellular mRNAs is clearly the most complex of the RNA classes. The protein products derived through translation of the transcriptome determine cellular phenotype. It is a result of this large complex population of mRNA molecules that a characteristic background smear is observed underlying the two dominant ribosomal species, when the products of an RNA extraction are submitted to agarose gel electrophoresis and then viewed using ethidium bromide fluorescence.

Given the complexity of the RNA population from even the simplest of organisms, it is critical that measures be taken to preserve that population prior to separation (or indeed any form of analysis). Since the solvent used to displace DNA during DNA chromatography and, as we shall see, RNA chromatography is acetonitrile, the integrity of RNA must be preserved in relatively high concentrations of the solvent and at elevated temperatures (75 °C). That this is the case was established by simply demonstrating that an RNA species exposed to a high concentration of acetonitrile retained its biological activity. Interestingly, when the effect of acetonitrile upon the activity of a typical ribonuclease enzyme was investigated at a range of solvent concentrations and temperatures, a marked effect upon the stability of the enzyme was observed. Thus, at 60 °C in 20% acetonitrile bovine, RNase is reversibly unfolded, whilst at 60% acetonitrile at the same temperature, the enzyme is unfolded, but in an irreversible manner. This observation suggests that RNA stabilization, or rather

elimination of the deleterious effects of contaminating RNases, will be afforded by the standard conditions employed in RNA chromatography.

In addition to the role of acetonitrile as a solvent in promoting RNA stability through RNase inactivation, the chromatographic separation of RNA isolated from tissues (as discussed below), eliminates RNase (as exemplified by bovine RNase) at low acetonitrile concentrations. Thus, as a consequence of the chromatography, RNase may be eliminated at least from the larger, more complex RNA species recovered from a biological extract.

4.3 Size-based RNA Separation

Figure 14 shows the application of RNA chromatography to effect the separation of a spectrum of RNA size standards that are commonly used in agarose gel electrophoresis. It appears at first glance that under similar denaturing conditions employed for the separation of single-stranded DNA, the RNA species are recovered in a size-dependent manner. However, as discussed earlier, the denaturation of double-stranded DNA (or indeed the chromatography of single-stranded DNA species) can produce anomalous retention times data. The additional peak in the chromatogram shown in the figure is a 451 nt RNA species that forms part of the human telomerase enzyme. The telomerase RNA elutes between the RNA size standards of 200 and 500 nt, somewhat earlier than would be ideally expected and with an asymmetrical appearance.

If one attempts to reconcile the chromatographic behavior of RNA (under these experimental conditions), with its structure and chemistry, there are a number of immediate inconsistencies. Size-based separation of double-stranded DNA is made possible by the structural uniformity and the shielded bases of the DNA double helix. Thus, the suppression of nucleotide sequence-specific hydrophobicity is achieved by forming an ion pair with the phosphate group and an ion-pairing

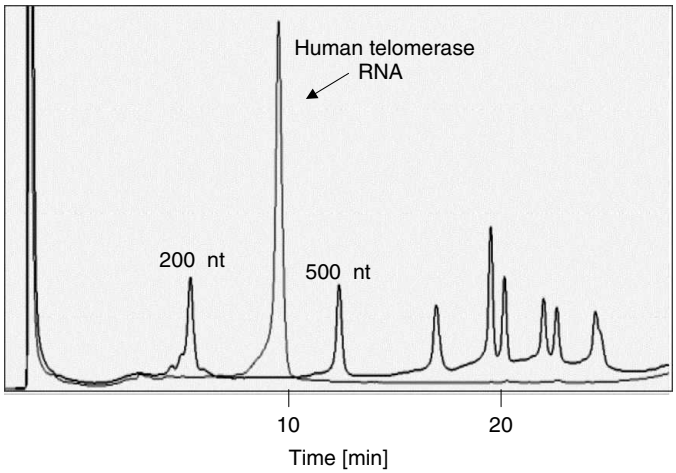

Fig. 14 Analytical separation of RNA size standards by RNA chromatography. The 451-nucleotide human telomerase transcript elutes between the 200- and 500-nt species as indicated.

reagent to establish the dominance of the tetraethyl moiety. The hydrophobic nature of the resulting molecule is responsible for the principal analyte–stationary phase interaction. Ion pairs of single-stranded DNA do not shield the more polar bases so separations of these molecules are not only strictly size dependent but are also based on polarity of the single strand.

Another example of the effect of the single-strand nature of a nucleic acid molecule on its retention in DNA chromatography is shown by the separation of homoduplex from heteroduplex DNA species. The increased single-strand character of a heteroduplex leads to a more polar molecule, which, in turn, reduces the retention time for the heteroduplex. This difference in retention time can be optimized by the manipulation of the temperature of the chromatography run.

Any DNA duplex can be considered as a negatively charged cylinder with a periodic distribution of hydrophobic patches. In some exceptional circumstances, as discussed above, polarity suppression is inadequate and this can prove useful, for example, in the enhanced retention of T-rich DNA following a bisulfite deamination and PCR in the analysis of DNA methylation. In the case of the separation of RNA species at elevated temperatures, it is instructive to note that electrophoresis of RNA under denaturing conditions (i.e. in the presence of urea or formamide gels) may not abolish all secondary and tertiary intramolecular interactions. Therefore, while some RNAs will be predominantly double stranded, some will be partly folded, and others still will be unfolded. In other words, it is impossible to predict what influence will be exerted by temperature and solvent parameters over the chromatographic behavior of complex RNA populations. Moreover, even solutions of single molecular species should not be assumed to be conformationally homogeneous. In the language of biological NMR spectroscopy, each RNA molecule will exhibit an ensemble of conformations defined by temperature, solvent chemistry, ionic strength and, in particular, the presence or absence of divalent cations. Ultimately, any given RNA species like a polypeptide chain will adopt its lowest free energy state(s), a process that is thermodynamically driven by the nucleotide sequence of that particular molecule.

Therefore, in considering the mechanism of size-based separation, a structure-specific factor must be considered. In addition, owing to the single-stranded nature of most RNA species (notwithstanding the formation of intramolecular double strands), there will be an unpredictable diversity in form in a biological RNA sample, making it very difficult to elaborate any rules for RNA chromatography. In fact, the separation of RNA in a size-based manner has much in common with gel filtration chromatography, perhaps in an analogous way that one can compare DNA chromatography in the size-based mode with SDS PAGE in the separation of polypeptides.

In the simplest description, there will be two modes of chromatography taking place when RNA is separated at, say, 75 °C. One of these components is equivalent to a denaturing mode (akin to the chromatography of single-stranded DNA) DNA chromatography, and the second will be a specialized form of hydrophobic interaction chromatography as the ion-pairing reagent produces a constellation of hydrophobic patches over the surface of folded and partially folded, complex RNA forms.

4.4 Separation of Cellular RNA Species

When a total RNA preparation is subjected to RNA chromatography, the resulting chromatogram is typified by that shown in Fig. 15. There are several distinctive features within the profile (obtained in this case at 75 °C) that are found in most biological preparations of this kind. The earliest eluting species include the population of tRNAs (and probably includes small nuclear RNAs), the middle section of the profile is dominated by the rRNA species, and finally underlying the entire chromatogram is a population of mRNAs centered on the later retention times. Corroboration of the above has been obtained in the case of the tRNA fraction by comparison with commercial tRNA preparations, for mRNA by RTPCR (see below) and for rRNA, by selectively enriching the polyadenylated mRNA population. Indeed, it is relatively easy to determine the retention time of any RNA species (from an organism whose genome sequence is available) by RTPCR, followed by nucleotide sequencing of the amplified product.

4.5 Separation of Messenger RNA from Ribosomal RNA

The expression of cellular phenotype is a direct result of the protein complement of a cell. The latter is, in turn, closely, but not inextricably, linked to the population of mRNA molecules produced by selective transcription of the genome in a given cell type. For this reason, there has been considerable interest in evaluating, both in a qualitative and quantitative manner, the products of transcription. The initial experiments in this field were gene specific, but more recently methods have been introduced that facilitate population-based experiments that often utilize microarray technology.

One of the key experimental procedures that forms the prelude to both of the above experiments is the systematic removal of rRNA from the mRNA (polyadenylated) fraction. Typically, the polyadenylated fraction is sequestered via an oligoT chromatography column or batch resin, the rRNA and tRNAs (together with the nonpolyadenylated mRNAs) are discarded and, after a suitable washing protocol, the

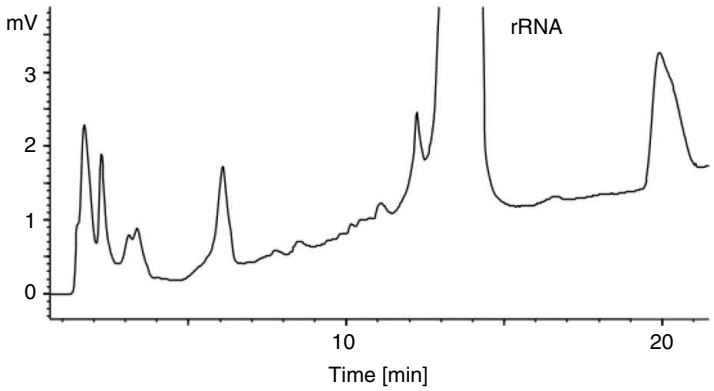

Fig. 15 RNA chromatography of a total cellular extract of RNA from tobacco plants. The large, broad peak eluting between 12 and 15 min is primarily rRNA together with mRNA.

mRNA fraction is concentrated and stored for subsequent experimentation. This procedure also forms the first step in the synthesis of cDNA from tissue samples and for the generation of template in a typical RTPCR experiment.

As can be seen in Fig. 16, the outcome of a typical mRNA purification can be readily followed by RNA chromatography. The process serves primarily to enrich for mRNA (or rather to deplete the rRNA) than to completely remove the excess rRNA. Indeed, at least two rounds of enrichment are usually required in order to remove the bulk of the non-polyadenylated RNA. In this particular experiment, RNA chromatography is used in an analytical mode for the evaluation of polyA mRNA purification. It is possible to apply the same principle in a preparative mode in order to produce a series of fractions that may facilitate the selective synthesis of cDNA populations for the production of size selected DNA libraries. In addition, one of the major drawbacks of polyA mRNA isolation is that some mRNAs are not polyadenylated and therefore will be excluded from any subsequent analysis. The use of RNA chromatography in a preparative mode therefore offers the potential for isolating at least a fraction of those mRNA species that do not co-elute with rRNA. This is clearly an important area for development, since the analysis of cell specific RNA populations in disease is becoming increasingly important in molecular medicine.

4.6 Analysis of Transfer RNA

Each cell contains a population (usually referred to as a *pool*) of tRNAs that meet the requirements of that particular cell's (or in the case of bacteria, that organism's) protein synthesis machinery. The range of sizes of tRNA molecules is particularly narrow, compared with mRNA, between around 60 and 100 nt, and a given cell typically contains around 100 species. While this molecular weight range is ideal for RNA chromatography, the close similarity of molecular sizes represents a problem for resolving individual components in a

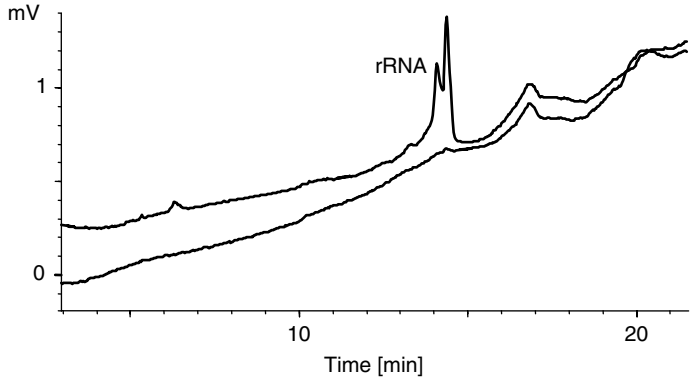

Fig. 16 Two cycles of polyA enrichment leads to the removal of the major contaminating rRNA species. The upper curve shows the RNA remaining (polyadenylated) after one round of enrichment on an oligo-dT resin and the lower curve after a second round.

typical cellular pool. This is readily seen in Fig. 17, where the total pool of tRNAs from *E. coli* has been subjected to RNA chromatography. Nevertheless, it is clearly possible to analyze fluctuations in tRNA pools by RNA chromatography when used in conjunction with a downstream procedure such as RTPCR.

It is also apparent that conformational differences between identical RNA molecules can be detected by RNA chromatography. In Fig. 18, the conformation of a single tRNA has been perturbed by changing the ionic composition and the temperature of the sample: the different elution profiles are a clear demonstration of the susceptibility of RNA chromatography to the conformation of the RNA molecule(s) under investigation. Therefore, there is a need to conduct a detailed systematic study of the temperature and solvent influences on the chromatography of complex RNA molecules: the tRNA population represents an ideal test bed for the development of a robust theoretical base for RNA chromatography.

4.7 Chromatography and Analysis of Synthetic Oligoribonucleotides

One of the major contributors to the rapid rate of progress in contemporary molecular biology has been the development of automated synthetic methods for the production of oligodeoxynucleotides. These relatively short (typically between 15–100 nt in length) oligomers are used in the PCR, numerous blotting procedures, transcription factor biochemistry, and, in some situations, have been shown to possess catalytic activity. The development of complementary protocols for RNA synthesis have been slower to emerge owing to problems arising through the presence of the additional 2′ hydroxyl group. Nevertheless, routine synthesis of 20- to 30-mer oligoribonucleotides is now possible. Such oligomers, as with DNA, have

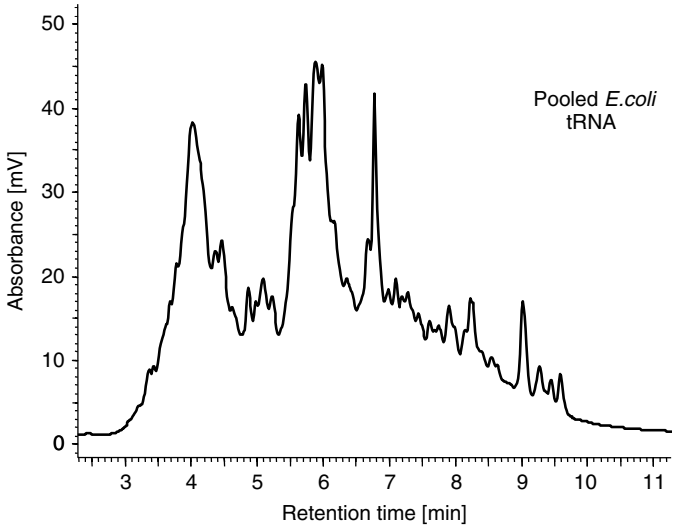

Fig. 17 RNA chromatography of the entire pool of tRNAs purified from *E. coli*. By coupling separation with RTPCR, it is possible to identify and quantify the individual tRNAs.

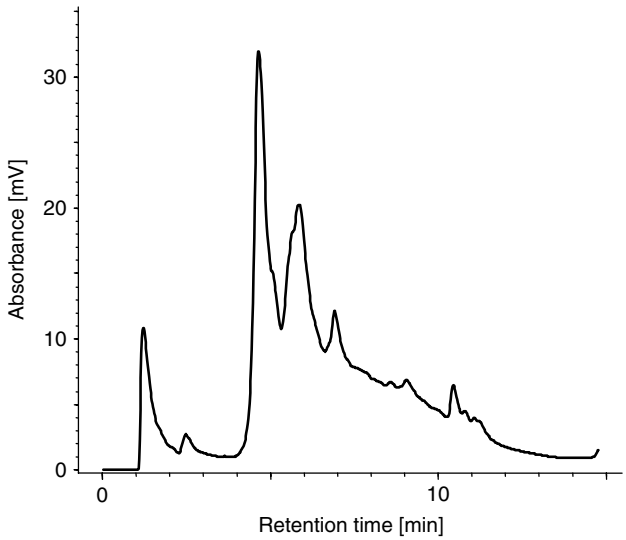

Fig. 18 Separation of the conformational species arising from preequilibration of an individual tRNA with Mg^{2+}. By systematically varying the buffer composition and temperature, RNA chromatography provides an insight into RNA conformation.

great value in experimental molecular biology, and are of particular importance in the study of catalysis mediated by RNA. Using the hairpin ribozyme as an example, RNA chromatography has been used as a general analytical tool in the study of the biochemical and conformational properties of synthetic RNA.

RNA is susceptible to acid–base hydrolysis, which provides a convenient means of optimizing conditions for the separation of oligoribonucleotides at single nucleotide resolution. The chromatogram shown in Fig. 19 is a 21 nucleotide synthetic oligoribonucleotides fluorescently labeled at its 5′ end, after exposure to 0.1 M sodium bicarbonate (pH 9 at 95 °C) for 30 min. The column was developed using acetonitrile (as described in the figure legend) and tetrabutylammonium bromide as the ion-pairing agent. The high resolution of the smaller cleavage products is apparent.

Base-catalyzed hydrolysis of RNA typically yields two products: a 2′phosphate moiety and a 2′-3′-cyclic phosphate intermediate, which undergoes further nucleophilic attack to yield the 3′-phosphate product. The 2′-3′-cyclic intermediate can be seen using 20% denaturing polyacrylamide sequencing gels (albeit with some with difficulty). However, with RNA chromatography, these two products are readily identified.

The information encoded by a typical genome is initially transcribed into mRNA and is subsequently translated into functional proteins, as discussed earlier. However, RNA also has the ability to catalyze biological reactions. This catalytic function is dependent on the three-dimensional shape of the RNA molecule. One technique that has been employed to obtain RNA structural information is ''RNA footprinting.'' This method provides information on solvent accessibility within RNA molecules

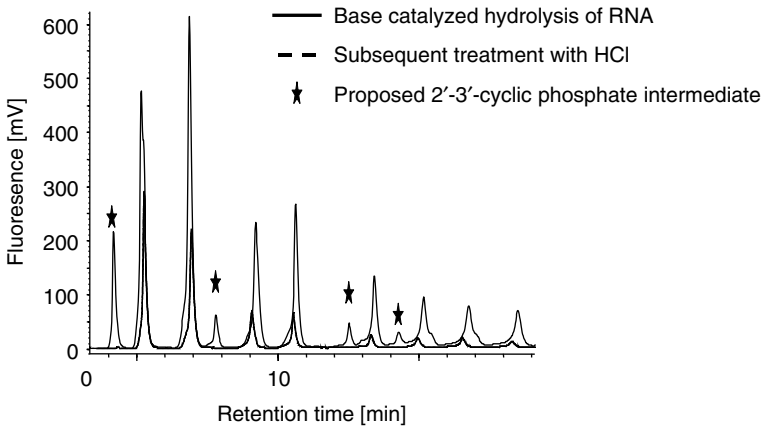

Fig. 19 The products of acid–base hydrolysis of a fluorescently end-labeled oligoribonucleotides. The 2′-3′-cyclic phosphate intermediate is indicated.

and can therefore be used to analyze secondary and tertiary interactions of small RNA structures. To differentiate between the internal and external regions of the folded RNA molecules, the solvent accessibility of the C5′- and also the generally quoted C4′-position of the ribose moiety can be monitored by the addition of an Fe (II)-EDTA complex together with hydrogen peroxide to the RNA in solution. The hydroxyl radicals generated primarily attack the C5′/C4′-position of the sugar, resulting in cleavage of the phosphodiester bond. The cleavage products can then be directly analyzed to identify those sites that show altered solvent accessibility.

Modifications to the standard footprinting reaction that allow the reaction products to be analyzed by RNA chromatography include the use of fluorescently labeled RNA. This allows the fluorescence-based detection of the cleavage products. The use of tetrabutylammonium bromide as the ion-pairing reagent is essential for the size-dependent separation of fluorescently labeled DNA. This regime particularly removes the influence of the hydrophobic fluorescent group and sequence-specific effects. Analysis of the footprinting products is rapid with run-times of approximately 30 min for each sample, with direct quantification of the cleavage products using proprietary software.

Keywords

Blot
A hybridization experiment in which the target nucleic acid is immobilized on a membrane (or filter). With electrophoretic separation of the target prior to immobilization, the blot is called a Southern blot if the target is DNA and a northern blot if the target is RNA.

Dissociation Temperature
The temperature at which two strands of a hybrid are 50% dissociated after a specified time.

Hybrid
A partially or completely double-stranded (duplex) nucleic acid formed by interaction of two single-stranded nucleic acids, either DNA or RNA. Reassociation or renaturation may be used to describe hybridization of completely complementary DNA or RNA strands.

Melting Temperature
The temperature at which 50% of the base pairs of a polynucleotide:polynucleotide hybrid or 50% of the strands of oligonucleotide:polynucleotide or oligonucleotide:oligonucleotide hybrids have dissociated.

Polymerase Chain Reaction (PCR)
A method for geometric amplification of nucleic acids employing two sequence-specific oligonucleotides complementary to the DNA strands and a DNA polymerase. Each cycle includes a denaturation step, a hybridization (annealing) step, and a polymerization step.

Strand Separation Temperature
The temperature at which the two strands of a polynucleotide duplex are dissociated.

Hybridization is the formation of partially or completely double-stranded (duplex) nucleic acid (DNA:DNA, DNA:RNA, or RNA:RNA) by sequence-specific interaction of two complementary single-stranded nucleic acids. Reassociation or renaturation are often used to describe hybridization between completely complementary DNA or RNA strands. Solution hybridization is an integral part of the polymerase chain reaction. Hybridization is often carried out using a labeled probe in an attempt to detect the existence and quantity of complementary sequence in a complex nucleic acid mixture. The target is often immobilized, as in Southern and other blotting techniques. This chapter deals with the physical chemical aspects of hybridization, in particular, thermodynamics and kinetics. Melting temperatures, hybridization rates, and dissociation rates and temperatures are interrelated. Details are provided for calculation of these useful properties and examples of calculations are provided.

1 Introduction

DNA:DNA, DNA:RNA, and RNA:RNA hybrid duplexes are the products of hybridization reactions between complementary single-stranded molecules. Reassociation or renaturation are often used to describe hybrid formation between completely complementary DNA or RNA

strands. The reverse reaction is called strand separation or dissociation. The structural differences between deoxyribose and ribose in DNA and RNA strands are reflected in different forms of the antiparallel double helices and in quantitative differences in hybrid stability and the rate of hybrid formation. Nevertheless, they are qualitatively the same, and the basic concepts will be treated together.

2
Stability of DNA:DNA, DNA:RNA, and RNA:RNA Hybrids

2.1
Melting and Dissociation Temperatures Defined

The four *different* temperatures defined below are associated with nucleic acid melting:

1. t_m^∞, the melting temperature of a polynucleotide duplex, such as a long DNA molecule.
2. t_{ss}, the strand separation temperature of a polynucleotide duplex, also called the denaturation temperature in PCR.
3. t_m, the melting temperature where at least one strand of the duplex is an oligonucleotide. The definition of oligonucleotide is somewhat arbitrary. Oligonucleotides of length 80 are offered for sale. For the purposes of this chapter, oligonucleotides will be defined by their melting behavior, where the dissociation occurs without the formation of stable intermediates.
4. t_d, the dissociation temperature for an oligonucleotide bound to a polynucleotide on a solid support, such as a blot.

Lower case t implies °C, whereas upper case T implies K ($T = t + 273.16$).

2.2
Stability of Polynucleotide Duplexes (DNA:DNA, DNA:RNA, and RNA:RNA)

Figure 1 illustrates the definitions of t_m^∞ and t_{ss} for polynucleotide melting. t_m^∞ is the temperature where the fraction of

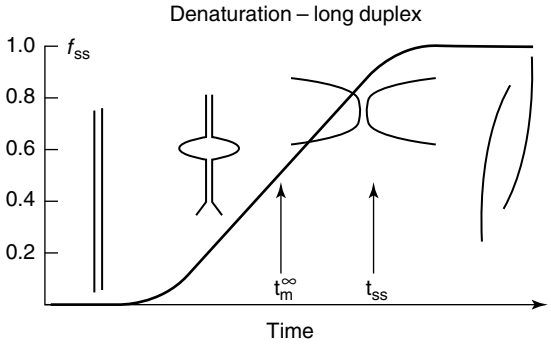

Fig. 1 Polynucleotide denaturation. f_{ss} = fraction single-stranded (nucleotides); t = temperature; t_m^∞ = melting temperature ($f_{ss} = 0.5$) for polynucleotides; t_{ss} = strand separation temperature. Steps in denaturation. (1) A duplex begins to denature reversibly at one end. End denaturation continues and internal loops are formed. At t_m^∞, the number of nucleotides in denatured ends and loops equals the number of nucleotides remaining base-paired. (2) Reversible denaturation continues until the strands are held together by the highest melting region. At t_{ss}, irreversible denaturation occurs. Superimposed on corresponding melting temperature profile (f_{ss} vs t) indicating t_m^∞ and t_{ss}.

single-stranded base pairs, f_{ss}, is 0.5, leading to molecules containing alternating duplex and denatured (loops or ends) regions. For natural nucleic acids, these loops may occur in the same places in many molecules, reflecting regions of lower melting temperature due to compositional heterogeneity. Because the reaction is intramolecular and equilibrium is rapidly achieved, t_m^∞ is independent of polynucleotide concentration and time, depending only on the composition of the polynucleotide duplex and the composition of the solvent. Strand separation occurs a few degrees above t_m^∞, at t_{ss}, and is not a rapidly reversible reaction. The denaturation temperature in PCR must be greater than t_{ss}.

For polynucleotides of length L containing only G:C and A:T or A:U base pairs, t_m^∞ (°C) may be determined from the empirical equation

$$t_m^\infty = A^* + 16.6 \log_{10}\left[\frac{[SALT]}{1.0 + 0.7[SALT]}\right] + B^* \cdot (\%\ G + C) - \frac{500}{L}$$

where $[SALT] = [Na^+] + [K^+] + [Tris^+] + 4[Mg^{++}]^{0.5}$. A^* is 81.5, 67, or 78 °C and B^* is 0.41, 0.8, or 0.78 °C/(% G + C) for DNA:DNA, DNA:RNA and RNA:RNA hybrids, respectively. For example, t_m^∞ for a 50% G + C DNA:DNA hybrid of length 250 in 0.05 M KCl, 0.002 M $MgCl_2$ ([SALT] = 0.23) is given by $t_m^\infty = 81.5 - 11.7 + 0.41 \times 50 - 2 = 88.3$ °C.

DNA:RNA hybrids adopt the A conformation of RNA:RNA hybrids rather than the B conformation of DNA:DNA hybrids but are always much less stable than RNA:RNA hybrids. However, DNA:RNA hybrids may be more or less stable than DNA:DNA hybrids, depending on % G + C. For example, in 1 M NaCl, t_m^∞ values for long DNA:RNA hybrids versus DNA:DNA duplexes are 103.2 °C versus 98.2 °C at 50% G + C and 87.2 °C versus 90.0 °C at 30% G + C.

Use of different solvents may affect A^* and/or B^*, and hence t_m^∞, with different effects for different polynucleotides. For example, A^* for DNA:DNA melting decreases 0.25 °C/% glycerol, 0.4 °C/% ethylene glycol, and 0.63 °C/% formamide. The effect of formamide on A^* is much less for DNA:RNA hybrids than for DNA duplexes, facilitating R-loop formation, where single-stranded RNA may displace a homologous DNA strand in a DNA duplex. In another example, base composition may be eliminated as a variable for DNA:DNA hybrids ($B^* = 0$) at 3.2 M Me_4NCl ($t_m^\infty = 94$ °C) or 2.4 M Et_4NCl ($t_m^\infty = 63$ °C) or 5.6 M betaine. Because betaine, unlike the quaternary ammonium compounds, is a zwitterion and does not neutralize the charge on DNA, the melting temperature may be varied from 75 °C down to 45 °C by varying KCl from 1 M to 0.01 M.

Introduction of modified bases also may affect A^* and/or B^*. Any substitution will affect either AT (or AU) or GC base pairs. If no charge change is introduced, the resulting change in t_m^∞ may be expressed as a change in A^*, ΔA^*, where

$$\Delta A^* = S(\%\ G + C)\, f_{AT}^M \quad \text{for A or T (U) modifications or}$$

$$\Delta A^* = S(\%\ G + C)\, f_{GC}^M \quad \text{for G or C modifications,}$$

where f_{AT}^M and f_{GC}^M are the fractional substitution of the modified base and S is characteristic of the nature of the substitution. For example, for 5-methyldeoxycytosine substitution for cytosine in duplex DNA, which may also occur in nature, $S = 0.12$.

Thus, for 100% substitution ($f_{GC}^{M} = 1$) in a 50% G + C DNA, t_m^{∞} is increased by 6 °C.

Formation of imperfectly matched hybrids also affects A*, t_m^{∞} being reduced approximately 1 °C for each percent mismatching. t_{ss} is proportionally reduced. Stringency in washing immobilized targets such as filters or blots (Southern, northern, slot) containing polynucleotide probes, a measure of selective dissociation of imperfectly matched hybrids, is increased as the temperature approaches t_m^{∞} in the wash solvent.

2.3 Stability of Oligonucleotide:Oligonucleotide and Polynucleotide:Oligonucleotide Duplexes

Figure. 2 illustrates the definition of t_m for the all-or-none melting of complementary oligonucleotides, with no denatured (frayed) ends or internal loops. t_m is the temperature at which the fraction of single strands, and hence single-stranded base pairs, f_{ss}, is 0.5. t_m is not t_d, the dissociation temperature important for washing of filters. t_d is discussed below in Sect. 4.

Because oligonucleotide melting is completely reversible, t_m, unlike t_m^{∞}, depends on oligonucleotide concentration as well as on nucleotide and solvent composition. Thus, for the same oligonucleotide in the same solvent, t_m determined spectrophotometrically at high concentration, t_m relevant for PCR priming at lower concentration, and t_m for filter hybridization at even lower concentration will be different. In a spectrophotometric determination of t_m, one oligonucleotide at molar strand concentration C_1 is often hybridized to a second complementary oligonucleotide at the same concentration. The molar concentration of the single-stranded fraction of the first oligonucleotide at t_m is $C_1/2$, which is equal to C in the calculations below. In the more common experiment, an oligonucleotide probe or primer is present at an excess concentration C_1 for saturation binding to a complementary region on a polynucleotide. The molar concentration, C, of the single-stranded oligonucleotide at t_m is C_1.

t_m for hybridization of excess oligonucleotide probe to a polynucleotide target is given by

$$t_m = \left[\frac{T^{\circ} \cdot \Delta H^{\circ}}{\Delta H^{\circ} - \Delta G^{\circ} + R \cdot T^{\circ} \ln [C]}\right] + 16.6 \log_{10} \frac{[SALT]}{1.0 + 0.7[SALT]} - 269.3$$

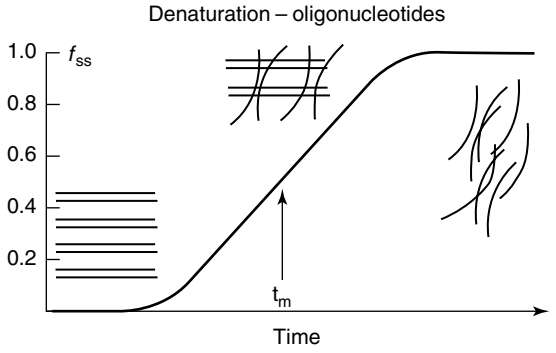

Fig. 2 Oligonucleotide denaturation. f_{ss} = fraction single-stranded (nucleotides and strands); t = temperature; t_m = melting temperature ($f_{ss} = 0.5$) for oligonucleotides. Steps in reversible denaturation with an all-or-none mechanism. At t_m, half of the duplexes have dissociated into single strands. Superimposed on corresponding melting temperature profile (f_{ss} vs t) indicating t_m.

where enthalpy $\Delta H^\circ =$

$$\Sigma_{nn}(N_{nn}\Delta H^\circ_{nn}) + \Delta H^\circ_e + \Delta H^\circ_i$$

and free energy $\Delta G^\circ =$

$$\Sigma_{nn}(N_{nn}\Delta G^\circ_{nn}) + \Delta G^\circ_e + \Delta G^\circ_i$$

and $T^\circ = 298.2^\circ K$ and R

$= 0.00199$ kcal/mol$^\circ$K

The first term in the t_m equation is T_m (K) in 1 M NaCl, the reference solvent. T is the reference temperature for the thermodynamic data tabulated below. The symbols i, nn, and e indicate contributions from initiation of base-pair formation, nearest-neighbors base pairs (stacking interactions), and other variables such as dangling ends, respectively. The use of nearest-neighbor thermodynamic functions is necessary because oligonucleotides with the same % G + C often have significantly different melting temperatures. Complete nearest-neighbor data sets are available for DNA:DNA, RNA:RNA, and DNA:RNA and chimeric RNA–DNA strands. The calculations below are illustrated for DNA:DNA, using as an example the parameters from Sugimoto et al. Several alternative parameter sets summarized in Owczarzy et al. give similar results. For the DNA:DNA nearest-neighbor values in the table below, $\Delta H^\circ_i = 0.6$ and $\Delta G^\circ_i = 3.3$ kcal mol^{-1} and NaCl:

$$-\Delta H^\circ = 10.9 + 8.8 + 5.6 + 6.6 + 8.0 + 9.4 + 11.8 - 0.6 = 60.5 \text{ kcal/mol}$$

$$-\Delta G^\circ = 2.43 + 1.79 + 1.07 + 1.11 + 1.47 + 1.8 + 3.15 - 3.3 = 9.54 \text{ kcal/mol}$$

$$R \cdot T^\circ \ln[C] = -8.2 \text{ kcal/mol}$$

$t_m = 32^\circ$C[in agreement with experiment]

Figure 3 depicts various measurements of the shape of all-or-none oligonucleotide melting curves (shown at the right). The measurement of the width of the melting curve, ΔT, based on the slope at the midpoint, is illustrated in the top panel.

$$\Delta T = \frac{\varphi R T_m^2}{\Delta H^\circ}$$

The value of φ is 4 if the oligonucleotide is present in excess. Thus, for the 8-mer above, $T_m = 273.16 + 32 = 305$ K. $\Delta T = 12.5\,^\circ$C. Thus, even several degrees above t_m, there is a significant fraction of hybrid. In PCR, extension by DNA polymerase may be initiated above t_m because extended products no longer dissociate, allowing all templates to be initiated eventually. When the complementary sequence is present at the same concentration (e.g. in a spectrophotometer), the melting curve

	AA or TT	AT	TA	CA TG	GT AC	CT AG	GA TC	CG	GC	GG CC
$-\Delta H^\circ_{nn}$	8.0	5.6	6.6	8.2	9.4	6.6	8.8	11.8	10.5	10.9
$-\Delta G^\circ_{nn}$	1.47	1.07	1.11	1.94	1.80	1.71	1.79	3.15	2.63	2.43

For example, consider excess 1 μM (GGATAACG) binding to (CGTTATCC) at 1 M

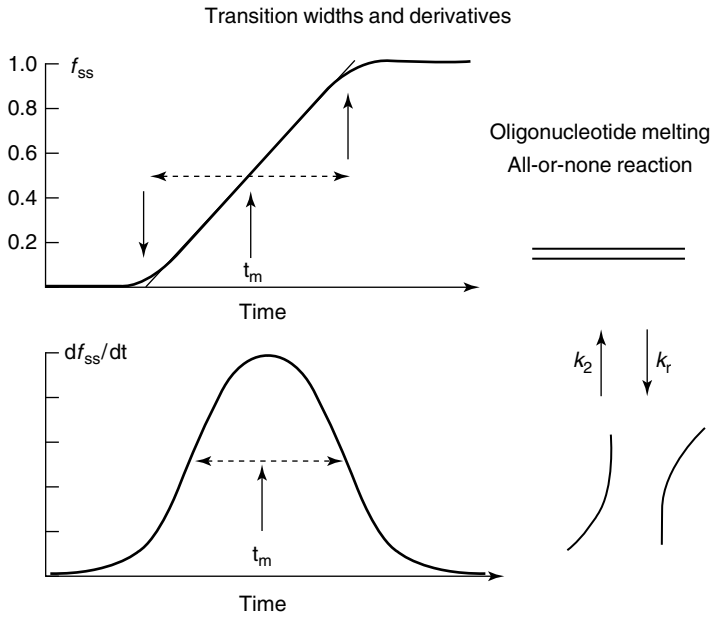

Fig. 3 Analysis of melting curves. f_{ss} = fraction single-stranded; t = temperature; t_m = melting temperature ($f_{ss} = 0.5$) for oligonucleotides; k_2 = second-order hybridization (reassociation, renaturation) rate constant; k_r = reverse first-order dissociation rate constant. Top: Melting temperature profile (f_{ss} 'vs' t) indicating t_m. The profile slope at the midpoint is used to create a straight line. The difference in t between the intercepts (noted by arrows) of this line at $f_{ss} = 0$ and $f_{ss} = 1$ is the transition width (dotted line). Right: Depiction of all-or-none oligonucleotide melting. Bottom: Derivative curve of df_{ss}/dt versus t also indicating t_m. The difference in t between the points where $f_{ss} = 0.5$ is the width at half-height of the derivative curve (dotted line).

is not completely symmetric about the melting temperature, and φ is increased to 6. The measurement of the width at half-height, $\Delta T_{1/2}$, for a derivative plot is illustrated in the bottom panel of Fig. 3.

$$\Delta T_{1/2} = \frac{-\varphi R T_m^2}{\Delta H^\circ}$$

The value of φ is 3.5 if the oligonucleotide is present in excess and 5.22 if the complementary sequence is present at the same concentration.

Because the nearest-neighbor thermodynamic functions have not been determined for most modified bases, the best available treatment is to calculate t_m in the absence of the modified bases (N/oligonucleotide) and to correct the result as follows:

$$\Delta t_m = -810000 \frac{NS}{\Delta H^\circ}$$

For example, substitution of 5-methyldeoxycytidine of deoxycytidine ($S = 0.12$) at three positions ($N = 3$) in the oligonucleotide example above (GGATAACG; $\Delta H^\circ = -60\,500$ cal mol^{-1}) gives $\Delta t_m = 5\,^\circ$C. An interesting modified base is 3-nitropyrrole, which interacts weakly but specifically with all four normal bases in

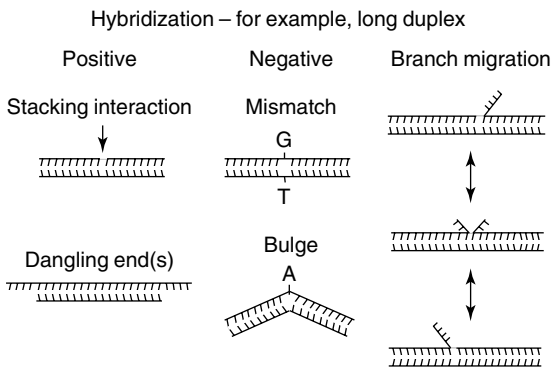

Fig. 4 Other contributions to the thermodynamics of oligonucleotide hybridization. Depictions of positive contributions. Top: Binding of an oligonucleotide adjacent to a duplex generates an additional stacking interaction (arrow). Bottom: Binding of an oligonucleotide to a longer strand generates 3′ and/or 5′ dangling ends. Depictions of negative contributions. Top: A GT base pair is used to illustrate a mismatch. Bottom: An inserted A in one of two complementary strands is used to indicate a bulge defect. Branch migration: The binding of two oligonucleotides with overlapping sequences to a complementary template generates a mixture of structures in which base-pairing by one and/or the other of the overlapping sequences interconvert by branch migration.

such a way that its inclusion in an oligonucleotide of length L leads to a melting temperature characteristic of an oligonucleotide of length $L-1$ but with a melting temperature almost independent of which base is pairing with the modified base. Oligonucleotides containing such a universal nucleotide have proven to be more useful than degenerate oligonucleotides for library screening and cloning by PCR when the genome comprising the library has not been sequenced.

Figure 4 illustrates other variables that may contribute to the thermodynamics of melting. There are two possible contributions that increase t_m, although the corrections are not large except for very short oligonucleotides. Very short oligonucleotides, 8 to 10 in length, have been used for array hybridization and as components of stacked primers for primer extension sequencing. Binding of an oligonucleotide adjacent to a duplex generates one additional nearest-neighbor (stacking) interaction, making an L-mer behave like an $L+1$-mer. The revised t_m may be calculated by adding the new nearest-neighbor contribution to the thermodynamic functions. Binding of an oligonucleotide to a longer strand generates 3′ and/or 5′ dangling ends. Their effect on t_m is strongly dependent on the orientation and sequence of the dangling end. Nevertheless, an estimated average contribution per dangling end may be taken to be $\Delta H^\circ_e = -5.0\ \text{kcal mol}^{-1}$ and $\Delta G^\circ_e = -1.0\ \text{kcal mol}^{-1}$, raising t_m for a 20-, 15- or 10-mer with one dangling end by an average 1, 1.5 or 3.0 °C, respectively. Filter hybridization typically involves two dangling ends. During the exponential amplification phase of PCR, one dangling end is formed upon primer-template binding, although PCR primers are typically too long for the dangling end to have a large effect.

Figure 4 depicts potential branch migration resulting from overlap (length O) of an oligonucleotide (length L) with a duplex. The total number of nearest-neighbor interactions is $L-O$, including the additional stacking interaction at the junction. The branch destabilizes the structure to

the extent of adding 0.8 kcal mol^{-1} to the free energy, lowering t_m for a 20-, 15- or 10-mer by an average 2.0, 2.6 or 3.6 °C, respectively. If the oligonucleotide overlap sequence is the same as the sequence in the adjacent duplex, branch migration can occur between all O possible structures. The branch migration stabilizes the structure to the extent of subtracting $RT_m\ln(O)$ from the free energy, canceling the destabilization introduced by the branch when the overlap, O, is about 4.

Figure 4 also illustrates variables that may contribute negatively to the thermodynamics of melting, including bulge defects and mismatches. Discrimination against these defects is a measure of the specificity of hybridization. A bulge defect may be estimated by calculating the thermodynamic functions without the bulge nucleotide and adding 2800 cal mol^{-1} to the free energy, lowering t_m for a 20-, 15-, or 10-mer by an average 7.0, 9.0, or 12 °C respectively. Mismatches may be approximated as follows. First calculate the thermodynamic parameters as if the mismatch had no effect. For example, if a GG mismatch occurs between G and G, one strand will contain GGG, with two GG stacking interactions and the other strand will contain CGC, with a CG and a GC stacking interaction. The entropy and free-energy contributions may be calculated by adding these four nearest-neighbor contributions and dividing the total by 2. Second, correct the thermodynamic functions depending on whether one of the mismatched bases is (1) a dG, (2) a dC, or (3) neither a dG or a dC. The enthalpies are corrected by adding 6700, 8700, or 9500 cal mol^{-1}, respectively. The free energies are corrected by adding 2900, 3700, and 4000 cal mol^{-1}, respectively. These corrections suggest that destabilization due to a mispair is of the order of the loss of two stacking interactions but with half the change in the temperature coefficient, although mismatches involving G residues are relatively more stable. A special case is a mismatch occurring at the end of an oligonucleotide, where only one stacking interaction can be lost. For internal mismatches, the average reduction in t_m for a 20-, 15-, or 10-mer would be 5, 8, or 12 °C respectively, if the mismatch contains a G, and 7, 10, or 16 °C respectively, if the mismatch contains a C, and 7, 10, or 17 °C respectively, if the mismatch contains neither a G or a C. These calculations are consistent with a decrease in t_m^∞ for polynucleotides of 1 °C/% mismatching.

3 Formation of DNA:DNA, DNA:RNA, and RNA:RNA Hybrids

3.1 Hybridization with Polynucleotides

Figure 5 illustrates a temperature profile for carrying out a denaturation and hybridization (renaturation, reassociation) reaction with polynucleotides. Denaturation requires a temperature above t_{ss}, the strand separation temperature. The hybridization reaction is initiated (time $t = 0$) by lowering the temperature to t_r, a hybridization (renaturation) temperature below t_m^∞, the polynucleotide melting temperature. Denaturation and renaturation of DNA also may be achieved by increasing the pH to approximately 13 followed by neutralization at t_r. The steps in the hybridization reaction are (1) a reversible nucleation step, in which the first 1 (or 2) correct base pairs are formed and (2) an irreversible zippering reaction, in which the subsequent base pairs are formed. Although duplexes containing fewer than 10 to 20 bp are usually unstable at t_r, the

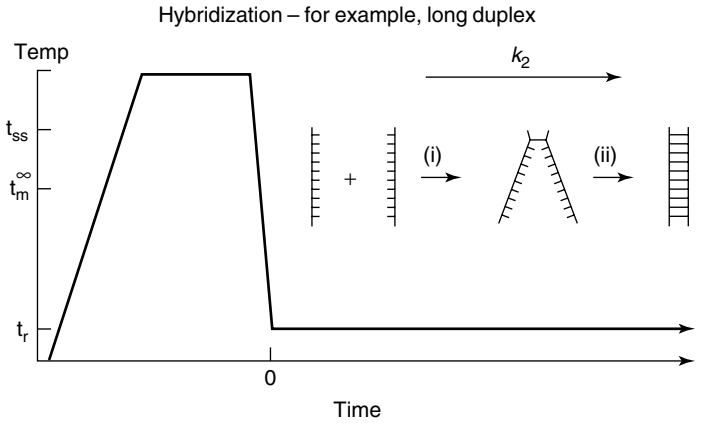

Fig. 5 Temperature profile for denaturation and hybridization as a function of time. t = temperature; t = time; t_{ss} = strand separation temperature; t_m^∞ = polynucleotide melting temperature; t_r = hybridization (renaturation, reassociation) temperature; k_2 = hybridization (renaturation, reassociation) rate constant. Denaturation occurs above t_{ss}. Hybridization is initiated ($t = 0$) and continued at t_r. Hybridization reaction steps: (1) nucleation; (2) zippering.

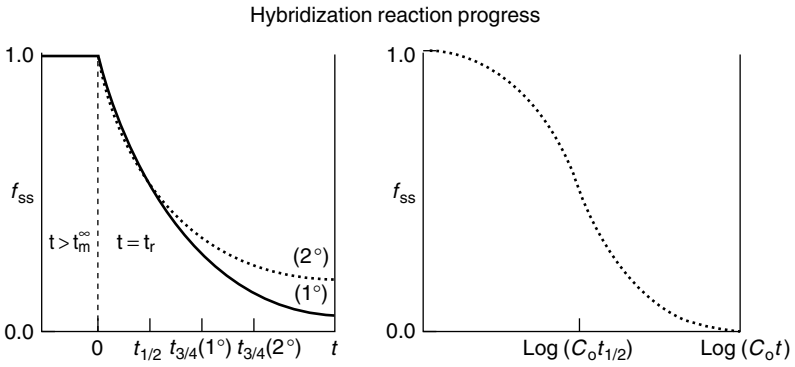

Fig. 6 Hybridization reaction measurements. f_{ss} = fraction of potential duplex remaining single-stranded; t_m^∞ = polynucleotide melting temperature; t_r = hybridization (renaturation, reassociation) temperature; C_o = total nucleotide concentration; t = time; $t_{1/2}$ = reaction half-time; $t_{3/4}$ = time to complete 3/4 of the reaction. Left panel: Reaction begins ($t = 0$) when t is decreased from $t > t_m^\infty$ to $t = t_r$. A second-order reaction (2°; dotted line) takes place if the complementary strands are present at equal concentration. A pseudo-first-order reaction (1°; solid line) takes place if one strand is present in excess over its complementary strand. Right panel: $C_o t$ plot of a second-order reaction.

rate-determining step is the formation of the second (or third) base pair. The overall hybridization reaction is characterized by the second-order rate constant, k_2.

Time course plots for the same hybridization reaction are illustrated in Fig. 6, including a $C_o t$ plot for a second-order reaction. Logarithmic $C_o t$

plots permit simultaneous display of reactions differing by orders of magnitude in half-time. Many reactions involve a labeled probe hybridizing to a complementary sequence in a complex target. If the concentrations of complementary probe and target sequences are unequal, the reactant in excess is termed the driver. A second-order reaction takes place if the complementary strands are present at equal concentration (e.g. DNA renaturation) or if the driver is double stranded and capable of reassociation. A pseudo-first-order reaction takes place if the driver is single stranded (e.g. mRNA) or cannot reassociate (e.g. immobilized on a solid support for a Southern blot). For all hybridization reactions, f_{ss} is the fraction of potential duplex remaining single stranded.

The concentration term used for polynucleotide hybridization is molar nucleotide concentration, C_o, and not strand concentration, C. For example, at 1 μg mL^{-1} double-stranded DNA, $C_o = 3$ μM. If one reactant is in excess, C_o is the driver concentration. When immobilized DNA is the driver, which is rarely the case, C_o is difficult to determine, being a measure of available target concentration. Furthermore, because a dilute probe would be used with the immobilized driver target, stirring may be necessary to maintain homogeneity.

Reciprocal rate plots are illustrated in Fig. 7 for the same pseudo-first-order and second-order reactions as depicted in the left panel of Fig. 6. These plots are described by the equations below.

Second Order: Half-time (seconds):

$$\frac{1}{f_{ss}} = k_2 \frac{C_o}{2} t + 1 \qquad t_{1/2} = \frac{2}{k_2 C_o}$$

Pseudo-First Order: Half-time:

$$f_{ss} = e^{-k_2 C_o t} \qquad t_{1/2} = \frac{\ln 2}{k_2 C_o}$$

For the second-order reaction, a plot of $1/f_{ss}$ versus t gives a slope equal to $k_2 C_o/2$. For the first-order reaction, a plot of ln $(1/f_{ss})$ versus t gives a slope equal to $k_2 C_o$.

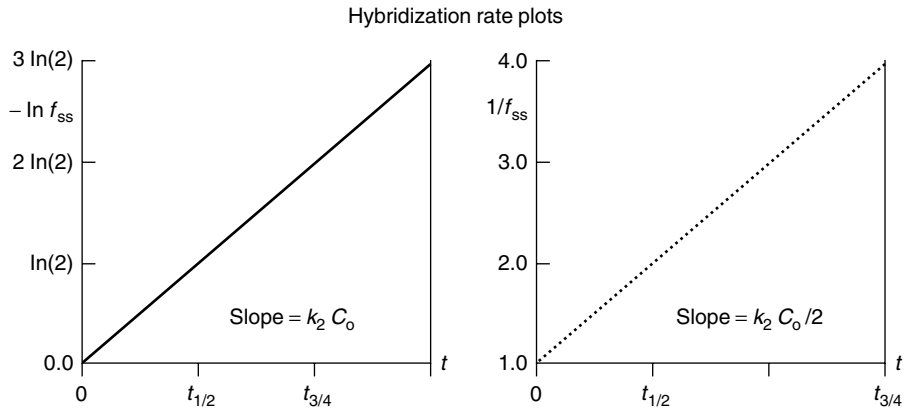

Fig. 7 Hybridization rate plots. f_{ss} = fraction of potential duplex remaining single-stranded; t = time; $t_{1/2}$ = reaction half-time; $t_{3/4}$ = time to complete 3/4 of the reaction. Left panel: Plot of $-\ln f_{ss}$ versus t for the pseudo-first-order reaction depicted in figure 6, left panel (solid line). Right panel: Reciprocal plot of $1/f_{ss}$ versus t for the second-order reaction depicted in figure 6, left panel (dotted line).

The second-order rate constant, k_2 in M^{-1} sec^{-1}, is given by

$$k_2 = \frac{k'_N \sqrt{L_s}}{N}$$

where L_s is the length of the shortest strand participating in duplex formation, N is the complexity or the total number of base pairs present in nonrepeating sequences and k'_N is the nucleation rate constant. The interpretations of N and L are illustrated in Fig. 8. The dependence of k_2 on the square root of L rather than on L suggests that nucleation sites become less available as the length of the single strands increases, consistent with an excluded volume effect.

The effects of temperature and salt on k'_N are illustrated in Fig. 9. The rate of hybridization reactions, and hence k'_N, is zero at t_m^∞. k_2 increases to a broad maximum at about 25 °C below t_m^∞. At lower temperatures, hybridization rates fall off slowly for homopolymers but precipitously for natural nucleic acids because of intramolecular base- pairing and consequent decreased availability of

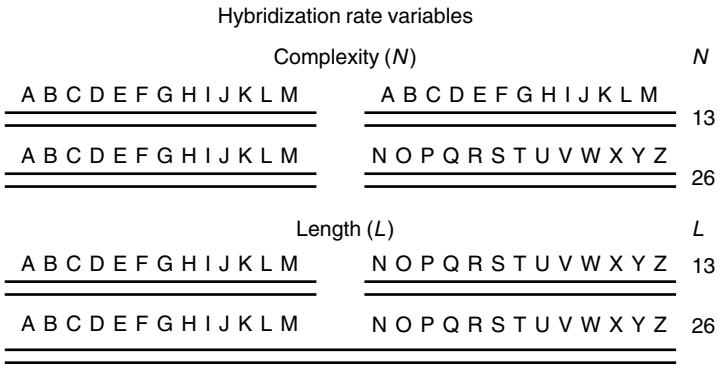

Fig. 8 Hybridization rate variables of the reactants. N = complexity, the number of nucleotide pairs of unique DNA; L = length, the average number of nucleotides in DNA single strands. Top panel depicts differences in N at constant L. Bottom panel depicts differences in L at constant N.

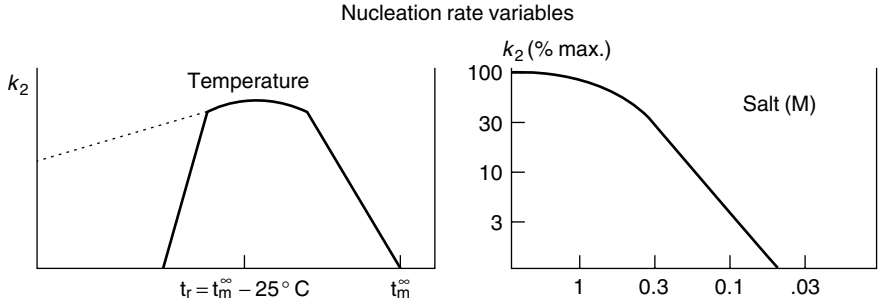

Fig. 9 Hybridization rate variables of the solvent. k_2 = hybridization (renaturation, reassociation) rate constant; t_m^∞ = polynucleotide melting temperature; t_r = hybridization (renaturation, reassociation) temperature. Homopolymers: dotted line; natural nucleic acids: solid line. Left panel: k_2 versus t_r. k_2 is 0 at t_m^∞. k_2 is maximum around $t_m^\infty - 25\,°C$. Right panel: k_2 versus salt (effective monovalent cation concentration).

nucleation sites. At optimal temperatures, k'_N for DNA:RNA hybrid formation is 20 to 50% slower than DNA:DNA hybrid formation, depending on the degree of RNA secondary structure. RNA:RNA hybridization rates are similarly reduced.

Although mismatched base pairs have a significant effect on melting temperature, mismatching of up to 10% of the bases has little effect on hybridization rates.

k'_N also depends on solvent viscosity and ionic strength. In solvents with glycerol, ethylene glycol, or formamide, k'_N is reduced because of increased solvent (microscopic) viscosity compared to 1.0 M NaCl at 70 °C. On the other hand, polymers, which increase the macroscopic viscosity, do not reduce hybridization rates. In fact, hybridization rates may be accelerated by use of dextran sulfate, which has the effect of concentrating the reactants. Another method for acceleration of hybridization is to concentrate the reactants at the interface of a phenol–water emulsion.

The dependence of k'_N on salt concentration is given by

$$k'_N = \{4.35 \log_{10}[\text{SALT}] + 3.5\} \times 10^5 \quad \text{for } 0.2 \leq [\text{SALT}] \leq 4.0$$

$$k'_N = \{4.35 \log_{10}(1 + 34[\text{SALT}]^3)\} \times 10^5 \quad \text{for } [\text{SALT}] < 0.2.$$

Thus, in typical hybridization buffers approximating 1 M NaCl, $k'_N = 3.5 \times 10^5$ M^{-1} sec^{-1}.

Consider, as an example, the hybridization of a nick-translated 4-kb probe ($N = 4000$) to a blot. The probe would be the driver. Assume that the nick translation broke the single strands to 625 nucleotides ($L^{1/2} = 25$). Then, in 1 M NaCl at 70 °C, $k_2 = 2.2 \times 10^3$ M^{-1} sec^{-1}. If the denatured probe is used at 10 ng mL^{-1} ($C_o = 30$ nM), $t_{1/2} = 2/k_2 C_o = 2/\{2.2 \times 10^3 \times 3 \times 10^{-8}\} = 3 \times 10^4$ s = 8.5 h. The half-times for hybridization may vary over many orders of magnitude depending linearly on the concentration and inversely on the complexity of the driver. For example, at 100 µg mL^{-1}, $t_{1/2}$ for the same nick-translated probe would be 3 s, whereas $t_{1/2}$ would be about 40 s, 1 h, and 30 days for λ ($N = 48\,000$), *E. coli* ($N = 4\,000\,000$), and human DNA ($N = 3\,000\,000\,000$) respectively.

3.2 Hybridization with Oligonucleotides

Hybridization with oligonucleotides usually takes place far below t_m^∞ (at or below t_m), so the decrease in k_2 near t_m^∞ is not a factor, and the temperature dependence of k_2 for oligonucleotides is small unless the target has interfering secondary structure. Oligonucleotide hybridization has the same salt dependence as polynucleotide hybridization. In fact, oligonucleotide hybridization may be described by the same equations. For oligonucleotide–polynucleotide reactions, the oligonucleotide is usually the driver leading to a pseudo-first-order reaction characterized by a rate constant with $N = L$ of the oligonucleotide. Oligonucleotide probe reactions are very fast. For example,

$$k_2 = \frac{k'_N}{\sqrt{L}} = 7 \cdot 10^4 \text{ M}^{-1} \text{ sec}^{-1} \text{ for a 25-mer in 1 M NaCl at } t_m^\infty - 25\,^\circ\text{C}.$$

k_2 is reduced only 1.2-fold for every 10 °C decrease in hybridization temperature. At 1 nM ($C_o = 25$ nM), $t_{1/2} = \ln 2/(7 \times 10^4 \times 25 \times 10^{-9}) = 396$ s or 6.6 min. Note that $t_{1/2}$ increases proportional to the degeneracy of mixed oligonucleotide probes or primers.

In other examples, $t_{1/2}$ for a 1 μM primer in PCR buffer ($k'_N = 7 \times 10^4\ M^{-1}\ sec^{-1}$) is 3 s and, in 1 M NaCl at t_m for 1 μM GGATAACG, the oligonucleotide used in previous thermodynamic calculations, $t_{1/2} = 1.3$ s.

4 Oligonucleotide Dissociation

Figure 10 illustrates oligonucleotide reactions on solid supports. Capture reactions are simply hybridization reactions. However, when hybridized oligonucleotides on solid supports are washed to eliminate unhybridized oligonucleotides, both t_m and the rate characterized by k_2 decrease as C decreases, and the hybrid stability depends entirely on the dissociation rate constant, k_r. In Sect. 2.3, we determined the enthalpy of melting, $-\Delta H^\circ$, and t_m, which is a measure of the equilibrium constant for oligonucleotide hybridization, or the ratio of the hybridization and dissociation rate constants. In Sects 3.1 and 3.2, we determined k_2, which has a small activation energy. With this information, we may determine k_r. The activation energy for k_r, E_a, is approximately 4.0 kcal mol^{-1} added to $-\Delta H^\circ$. t_d is the dissociation temperature, which may defined as the temperature at which 50% of correctly matched hybrid is released in a specified length of time, t_{wash}. Because t_d depends on time and not on concentration, unlike $t_{1/2}$ for hybridization and t_m, t_d is the same whether using unique or degenerate probes. It is t_d may be estimated for extended washing of 14- to 20-mers as 2 °C for each dA:dT pair plus 4 °C for each dG:dC base pair. t_d may be calculated using the following:

$$t_d = \frac{T_m}{\{1 + R \cdot T_m \cdot [\ln (t_{wash}/t_{1/2})/E_a]\}} - 273.2$$

For example, for 1 μM GGATAACG with no dangling ends in 1 M NaCl, $E_a = -\Delta H + 4000 = 64\,500$ cal mol^{-1}, $T_m = 305$ K (Sec. 2.3), and $t_{1/2} = 1.3$ s (Sect. 3.2). $t_d = 10$ °C for 50% probe released with 1 h (3600 s washing. As another example, $t_d = 48$ °C for 6 h of washing for the arbitrary 16-mer GATCGTACCAAGGTTC with 2 dangling ends, in agreement with the 2 °C for each dA:dT pair plus 4 °C for each dG:dC base-pair rule. These calculations depend on all the elements of the physical chemistry of hybridization.

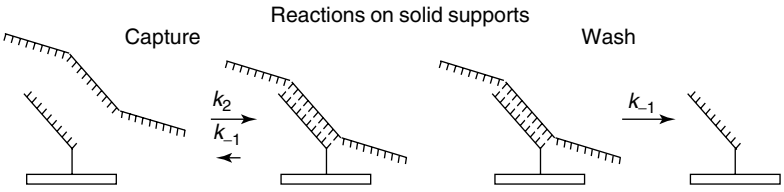

Fig. 10 Reactions on solid supports: hybridization (capture) and dissociation (washing). k_2 = second-order hybridization (reassociation, renaturation) rate constant; k_r = reverse first-order dissociation rate constant. Left: Capture of a polynucleotide by an oligonucleotide tethered to a solid support. Below the melting temperature, the hybridization rate is faster than the dissociation rate. Right: Dissociation of captured product. No hybridization occurs if unreacted polynucleotide is washed away. The reaction is governed by k_r.

Keywords

Bacterial Lysis
Bursting of bacteria and the release of their contents.

Bacteriophage Plaque
Single bacteriophage particle-derived clearing in a continuous, gel-embedded, turbid slab of bacteria.

Bacterial Transduction
The use of bacteriophages to introduce new properties to bacteria.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 9

Bacteriophage Therapy
The use of bacteriophages for controlling/eliminating unwanted bacteria.

Capsid of a Bacteriophage
Protein shell with a cavity in which a bacteriophage genome is packaged during formation of a mature bacteriophage particle.

Concatemer
Linear polymer of a bacteriophage's double-stranded DNA genome.

Connector (Portal Ring)
Ring of (usually) 12 subunits through which a DNA molecule enters a capsid during DNA packaging.

DNA Packaging Motor
Terminase-containing, ATP-fueled complex that drives a DNA molecule into a bacteriophage capsid.

Lytic Bacteriophage
A bacteriophage that causes lysis of its host.

Lysogenic Bacteriophage
A bacteriophage that coinhabits its host.

Nanometry
Measurement of nanometer-sized movements.

Prophage
A bacteriophage genome that replicates with a host cell.

Procapsid
The bacteriophage capsid immediately after it is assembled and before it begins to package a DNA molecule.

Sodium Dodecylsulfate Polyacrylamide Gel Electrophoresis (SDSPAGE)
Gel electrophoresis of proteins whose surface charge density has been homogenized by boiling in sodium dodecylsulfate.

Tail of a Bacteriophage
External projection of a bacteriophage capsid that attaches the bacteriophage to host cells.

Terminase
A multimeric protein complex that forms at least an ATPase of a DNA packaging motor.

Transcription
The process of transferring information from a DNA genome to RNA.

Translation
The process of using information encoded in RNA sequence to synthesize a specific protein.
